Some Observations on Inherited Physical and Psychical Characteristics in Tuberculous Patients*

F. M. POTTENGER, M.D.

Monrovia, California

There is a time when practically every tuberculous infection of the lung of the adult type can heal. The necessity of confining this statement to the adult type of tuberculosis is selfevident to students of the subject but may not be so readily understood by others.

The adult type is the chronic type. It is the type in which the disease occurs after the body has already fought a successful fight against an infection (the early infection of childhood), as a consequence of which it has emerged from the combat with an increased specific resistance against the tubercle bacillus and an ability to combat future infections with greater success. Nearly all tuberculosis in the adult population in civilized countries belongs to this type.

There is another type of tuberculosis which we call the childhood type. It takes an acute form and runs a rapid course. It is best illustrated by the disease as found in children during the first and second years of life. It is also the type that is found among the primitive races when the disease is first introduced among them, such as was illustrated by the American Indians and the Icelanders when the white people first carried infection to them. It is also occasionally seen in adult members of our population, where it appears as acute generalized tuberculosis. This is a type which is opposed by no or apparently little specific resistance on the part of the patient. It spreads rapidly and has the characteristics of an acute infection, while the usual disease of the adult type is that of a chronic infection.

While it may be truly said that there is a time in the life history of nearly every adult type of tuberculous infection, when the host has the power within himself, if properly conserved, to overcome it, it may be said with equal truth that there is rarely a time when the host has it within his power to overcome tuberculous infection of the acute or infantile type.

In attempting to treat tuberculosis successfully it is the adult type in which we are particularly interested. The greatest problem in its success is to bring the patient under treatment at a favorable time, when healing is possible, and to keep him under treatment sufficiently long for healing to take place. In other words, the problem has two phases as far as the physician is concerned; one, the skill to make an early diagnosis; the other, that of understanding and mastering the individual whose body harbors the tuberculous infection so that he will do his part in bringing about a healing.

In this connection it must be said of the adult type of the disease that the attitude of the patient has far more to do with the success of treatment than the tendency to heal or not to heal on the part of the disease. Chronic tuberculosis has a decided tendency to heal. This is evident from the fact that it has become a chronic disease, while its natural course in infants and in unprotected adults is that of an acute process. The reason so many die of tuberculosis is not because it will not heal, but because they ignorantly or knowingly prevent it from healing by the manner in which they comport themselves.

Regardless of what has just been said of the curability of early tuberculosis of the chronic type, there is a great difference in the resistance of different individuals to tuberculosis. Resistance seems to be an individual matter. While nearly all can overcome small infections, and some can overcome massive infections, there is quite a large group of individuals who are not able to obtain a satisfactory healing if the disease becomes moderately advanced. We do not know in what this difference consists, but it is undoubtedly something fundamental in the body and its reactions.

As I study the problem of tuberculosis I am ever more convinced that the pendulum has swung too far to the side of the bacillus and its accompanying anatomicopathological changes. Tuberculosis is, after all, a biological question and bound up with the inherited qualities of its host; and, while tubercle bacilli are the actual producers of the disease and may show variation in virulence in different strains, there are undoubtedly, on the other side, variations in strains of individuals, differences in resistance inherent in them which cause one to succumb to a relatively small infection and permit another to withstand and suffer apparently little inconvenience from a widespread lesion. In other words, heredity is an

*Read before the twenty-sixth annual meeting of the American Therapeutic Society, Atlantic City, May 22-23, 1925.

Copyright, 1926, by A. R. Elliott Publishing Company.

important factor in determining the incidence of tuberculosis as well as its curability when the infection has once become a clinical entity.

Constitutionally inherited characteristics of body cells undoubtedly determine to a large extent the degree of infection and the rapidity of its spread. In other words, the manner in which the bacillus comports itself when it enters the host is probably determined, all other factors being equal, by something which is transmitted to the individual through the germ plasm.

The extent to which clinical tuberculosis depends upon environment and the extent to which it depends upon inherited characteristics cannot be told. Contact with bacilli is essential to infection. Living in bad environment aids the bacillus in establishing disease. But back and beyond both of these is a determinant with which we must reckon.

HEREDITY

It has been shown that persons suffering from clinical tuberculosis have a much greater amount of tuberculous disease in their blood relations than the nontuberculous. Raymond Pearl (1) collected data on this point from fifty-seven family histories, thirty-eight tuberculous and nineteen nontuberculous, the entire number of persons investigated being over five thousand. The history of the tuberculous showed seven per cent. of blood relatives tuberculous, while that of the nontuberculous showed only one and two tenths per cent. In other words, there were six times as many cases of tuberculous disease among the members of the families of the tuberculous as there were among those of the nontuberculous. This percentage of difference cannot be accidental, nor can it be accounted for alone by the fact of greater opportunity of infection. In the fifty-seven histories analyzed by Pearl, he says: "In any case the close contact rate is higher for the tuberculous offspring than it is for the nontuberculous offspring. In other words, these figures indicate that familial contact with active open cases is beyond question a factor in determining the incidence rate of clinically active tuberculosis. It appears equally obvious, however, that it certainly does not account for the whole of the increase in the incidence of the disease which we find to occur as the amount of tuberculosis in the immediate direct ancestry increases."

Not only must we look for the cause of susceptibility to the bacillus in the realm of physical characteristics, but we must recognize that it may also have as its ally certain hereditary psychical peculiarities. I have long noticed that many tuberculous patients manifest certain psychological traits. While we see many heroic struggles made by those suffering from tuberculosis which command the admiration of all who come in contact with them, yet one must recognize that this struggle is not only with the disease but also with the patient's own emotional traits. There is a tendency on the part of many tuberculous patients to be imbued with a spirit of fear; to shrink from the responsibility of life and life's problems and to become selfcentred. They fear their ability to regain health and to maintain it when once attained. They fear exertion. They fear business. They fear the strain of life in general. They shrink from tasks that a normal healthy individual would accept without hesitation. They assume an attitude of dependency which greatly reduces their efficiency. They often become unmindful of the rights of others. All this seems to show a reversion to childhood traits. I have thought of these characteristics as being due to the effect of the disease, but whether they are effects of the disease or whether they are traits which are submerged until brought out by the stress of the disease is not wholly clear. There are undoubtedly many people who under ordinary conditions of health, happiness and economic success are leading normal lives and meeting life's problems in a satisfactory manner whose margin of physical and psychical safety is very narrow. When a disease like tuberculosis comes upon them, producing its harmful effects upon the physical body and, at the same time, adding its cares and worries, with its blasting of hopes and ambitions, its upsetting influence on domestic, business and social relations, their margin of safety is exceeded; their physical and psychical equilibrium is upset, and the particular psychic qualities which were present, though held in abeyance, now manifest themselves.

Some students of psychology believe that this psychic type is the one that is particularly prone to tuberculosis, and that the psychological manifestations here described as manifesting themselves as a result of the disease are primary and have something definite to do with the development of clinical tuberculosis. This is the type of regressive personality; the type that turns to shelter; the type that meets stress but poorly, be it an excessive physical or mental strain, or be it an infection. Mühl (2 and 3) has recently contributed two important papers bearing on the psychical traits of tuberculous patients. She believes that the personality is primary, that it antedates and is a factor in the causation of the disease. The emotional traits present cause a prodigal misuse of energy which weakens the individual and makes him susceptible to the disease.

In the treatment of tuberculosis success is greatly augmented by an understanding of the patient and his emotions against which he is obliged to struggle. The psychical side of the tuberculous patient requires and demands as much care and consideration as the physical side; for harmful stimuli which are capable of upsetting the normal physiological equilibrium of the patient may arise as well from one source as the other.

Future study of tuberculosis and the tuberculosis problems can well be directed toward the question of type. Patients must be studied from the viewpoint of the nervous, psychological and endocrinological types. Their general cellular resistance must be observed. These factors must not only be taken into consideration in the individual, but in his forebears as well.

Prostatic Massage as a Prophylactic Measure in Acute Gonococcal Infections of the Anterior Urethra

ABR. L. WOLBARST, M.D.
New York

In a recent contribution (1) on the subject of the obstinate gonococcal infections in the male genital tract, I made reference to a study of the prostate and seminal vesicles in a series of more than one hundred cases of acute anterior gonococcal urethritis (first infections) in which there was no clinical evidence of posterior involvement. In about thirty per cent. of the cases thus studied, it was found that the prostate was enlarged, soft and congested; and although the urine voided in two glasses (Thompson test) showed a clear second glass, the urine voided after gentle massage of the prostate revealed the presence of varying amounts of mucus and pus, but no gonococci. In other words, there was unmistakable evidence of the existence of a low grade, nonvenereal, chronic inflammation in the prostate, without clinical symptoms other than those characteristic of the acute infection in the anterior urethra; in a smaller percentage, the seminal vesicles likewise showed evidence of chronic inflammation. This condition was accounted for as the result of genital trauma, either in the form of excessive sexual indulgence, masturbation or withdrawal, practised for long periods.

I considered these findings a rational explanation of those not uncommon cases which run their course as a simple uncomplicated anterior infection and then without warning symptoms of any kind suddenly or gradually appear as a low grade posterior infection with a most annoying tendency to chronicity and often to serious complications. It appeared quite clear that there was a direct and insidious connection between the low grade preexisting nonvenereal inflammation in the prostate and the sudden inexplicable manifestation of the gonococcal infection in the posterior adnexa after the case seemed to have run its course as an uncomplicated anterior urethritis. Furthermore, it was felt that it would constitute a distinct advance in our therapy if advantage could be taken of the information derived by these data to the end that these extensions of the infection to the posterior adnexa might be prevented by the adoption of suitable prophylactic measures.

Quoting: "If therefore the adnexa are compromised in advance of and independently of the gonococcal infection in about thirty per cent. of cases, we can readily understand why the inflammatory process spreads quickly to these organs and steadily persists as a low grade infection, presenting no acute symptoms and strongly resistant to usual therapeutic measures. If this observation can be confirmed by additional study of a large number of cases, it might be desirable to examine the prostate and seminal vesicles in every acute anterior case, in the hope of instituting appropriate treatment towards reducing any existing inflammation or congestion in these organs. It is a matter of grave doubt in the writer's mind whether such a prophylactic measure is feasible in the presence of an acute infection in the anterior urethra, but the question can be answered only by careful and patient experimental study. If the suggestion is a practical one, it would appear that many of these obstinate posterior cases might be prevented by this means." (loc. cit.)

Prophylactic massage of the prostate in anterior urethritis not only sounds a new and untried note in our treatment of male gonococcal infections, but is diametrically opposed to the usually accepted dictum that there is serious danger in any manipulation of the adnexa in the presence of an acute anterior infection. Never having seen any reference in the literature, to the advisability of this procedure, I made the suggestion rather reluctantly, in the hope that others might be attracted to its possibilities and report the result of their observations.

The procedure was adopted as a routine measure in my practice and the results seem to have justified the experiment beyond any doubt. The number of cases thus treated (forty) is not large enough to warrant a definite conclusion, but there is sufficient satisfactory evidence to justify a continuance of the procedure and to recommend its adoption by others. In not a single instance has there been any visible extension of the inflammation to the posterior urethra, and in a goodly proportion of cases the preexisting congestion has been relieved and improved.

It cannot be gainsaid, of course, that an identical result might have been attained without the massage of the prostate; nevertheless, in view of all the circumstances it is fair to assume that the massage must have had a tonic effect on the organ because of the increased blood supply thus induced, with the resulting consequent augmentation in the power of the prostate to resist the bacterial invasion from the anterior urethra. It should be emphasized that one should not forget the element of danger associated with this procedure. Even in normal cases, prostatic massage is not devoid of harmful consequences, if performed carelessly or violently or too frequently; but I believe there is little to be feared if the procedure is carried out gently and cautiously, and with due regard to the presence of the infection in the anterior urethra.

It is of interest to note that these observations have been fully confirmed by Wohlstein, of Bad-Pistyan, Czechoslovakia (2). In a clinical report giving detailed data of a number of cases of urethral infection, he states that chronic prostatitis has been observed in quite a large number of cases of acute anterior infection without any evidence of posterior involvement, and he expresses the opinion that such instances are much more frequent than is generally assumed. He urges careful examination of the prostate in every affection of the urethra.

Furthermore, he also advocates massage of the prostate as a prophylactic measure against the spread of the infection in acute anterior cases. He does not wait until the signs of posterior involvement appear, but in every case of acute anterior urethritis he begins

to employ massage of the prostate at the end of the second week, even though there be no evidence that the infection has extended to the posterior urethra. In all cases thus treated, he has not encountered one case in which the prostate became involved in the inflammatory process. He expresses the opinion that the effects of prostatic massage are not purely mechanical, but that it induces an increased flow of blood to the organ, and because of that fact, the prostate is better able to resist any threatened bacterial invasion from the anterior urethra.

I have adopted the following technic: The patient presents himself with a full bladder, and voids in two glasses, retaining the balance of the urine in the bladder. The prostate is then gently and cautiously massaged, and the urine remaining in the bladder is voided in a third glass. This is followed by the treatment for the anterior urethritis. The massage is given every four or five days and is continued so long as the prostate shows evidence of the chronic inflammation.

SUMMARY

Unsuspected nonvenereal chronic inflammation of the prostate and seminal vesicles is quite commonly encountered in probably thirty per cent. of cases with first urethral infections.

The presence of this low grade inflammation accounts for those difficult cases in which a mild anterior urethritis suddenly emerges as an acute or subacute prostatitis with a tendency to chronicity and complications.

As a prophylactic procedure, the prostate and seminal vesicles should be examined in every case of anterior urethral infection.

If the prostate is found congested—large, soft and boggy, gentle massage carefully performed, may act as a prophylactic against the extension of the inflammation to the adnexa, at the same time reducing the preexisting chronic congestion in the organ.

The value of this procedure has been demonstrated in a fairly large number of cases, which justifies its recommendation for further observation by urologists.

Cutaneous Tests with Suspensions of Treponema Pallida*

HENRY W. PATTON, M.D.
STAIGE D. BLACKFORD, M.D.
and DUDLEY C. SMITH, M.D.
Charlottesville, Va.

Since the publication of Noguchi's first article (1) on luetin in 1911, much literature has appeared on the subject and the reaction, as a diagnostic test for syphilis has been both cricitized and defended. Many workers, soon after its introduction, confirmed Noguchi's results. But later observers have failed to do so and, in spite of its fairly universal recommendation in textbooks, its use has been practically abandoned.

Sherrick (2), in 1915, showed that potassium iodide administered orally would cause positive luetin reactions in normal persons. Furthermore, he found that intradermal injections of agar, starch, and other substances would give similar results in nonsyphilitic patients receiving iodine containing drugs. Cole and Paryzek (3), in 1917, demonstrated that certain salts other than potassium iodide would influence the luetin reaction in the same manner.

In 1922, Kolmer and Greenbaum (4) found that luetin and ascitic agar gave reactions of the same degree and of the same kind. They further found that a saline suspension of Treponema pallidum did not yield allergic reactions: "reactions occurring among syphilitic patients were sometimes slightly larger and better defined than those occurring in healthy subjects, but the differences were slight and of no diagnostic significance." They ascribed the reactions occurring among syphilitic patients following intracutaneous injections of old luetin, the control fluid or vaccine of treponema to nonspecific and physical processes of antiferment action. Smith and Gill (5) corroborated their work in regard to the reactions of luetin and ascitic agar in syphilitic and nonsyphilitic patients.

The purpose of our experiment was to repeat that part of the work of Kolmer and Greenbaum in which they used a saline suspension of Treponema pallida freed from culture media, and to supplement this by using a similar suspension in one twentieth normal sodium hydroxide. It seemed possible that if the protein of the treponema could be put into solution, a more effective reaction would be obtained. Sodium hydroxide was suggested because of its use in skin protein sensitization tests for hay fever and asthma.

The H. K. Mulford Laboratories very kindly furnished us the saline suspension, prepared as follows: "The treponema are planted in flasks of serum bouillon and incubated for approximately two months. If, on microscopic examination, sufficient growth has taken place and the purity of the growth established, the culture is centrifugalized at a low speed for the purpose of throwing out heavy particles. The culture is then centrifugalized at a high speed, the sediment is separated from the supernatant fluid, and emulsified in saline solution. The sediment is washed in this manner by centrifugalization and resuspended

W=Typical wheal with negative control.

in saline at least three times to rid the treponema of culture media. The final suspension should reveal approximately twenty to thirty treponema to the dark field. Five tenths per cent. phenol is added as a preservative."

The sodium hydroxide suspension was prepared by mixing equal quantities of the saline suspension and one tenth normal sodium hydroxide. In about half the cases, this mixture was used at once; and in the remainder, the alkali was allowed to act on the treponema for varying periods up to one month. It was found that the use of solutions of sodium hydroxide stronger than one twentieth normal caused such an inflammatory reaction in the skin as to interfere with the test.

All of our cases were tested with the alkaline material and eighty-seven of the one hundred with the saline suspension also. A control of one twentieth normal sodium hydroxide was carried in every case. At first, controls of normal saline were used in addition, but it was later deemed unnecessary to continue this procedure.

The three injections were made simultaneously, the suspensions containing treponema being used on the upper and lower left arm and the control on the lower right. Sufficient fluid was injected intradermally in each case to raise a small superficial vesicle. The amount used for each test was approximately 0.04 c. c. Aseptic precautions were employed throughout.

Observations were made within two hours following the injections, daily thereafter for the first week, and on alternate days during the second week. In many instances they were more frequent. A number of patients left the hospital before the expiration of the two week period of observation, but in all of these the reaction had completely subsided. No delayed reactions were observed in any of the 187 tests. The observations were made by two different examiners on alternate days.

After the completion of 139 tests as outlined, it became apparent to us that neither of the two preparations used gave promise of clinical usefulness. In view of the work of Sherrick cited above in which it was shown that agar and various other materials gave positive skin reactions in patients receiving iodides, we attempted to determine if such reactions would be given by treponema freed of extraneous material. Accordingly, twenty-two patients without any evidence of syphilis were given twenty grains of potassium iodide three times a day for a two day period prior to injections and throughout the period of observation. The remainder of the technic used in these cases was the same as that already described.

In the following tables those patients who gave a positive Wassermann reaction, a characteristic history of syphilitic infection, or clinical signs of the disease were designated as syphilitics. Those showing none of the foregoing indications were regarded as nonsyphilitics. In the table of individual cases (Table I), the evidence of syphilis in each case is recorded.

It should be stated that the skin reactions were in no cases as marked as those pictured in Noguchi's original article. In two cases the reactions were definite, a wheal appearing at the site of both the treponema injections and lasting two or three days, while the control test remained absolutely negative. Both of these cases gave negative Wassermann reactions, but one of them gave the history of a chancre forty years previously and had an aneurysm of the aorta. The other was an intern in whom there was no reason to suspect syphilitic infection.

There were, however, differences noted in several instances (Table 1) between the reactions to the treponema and the control injections. These differences consisted of an increase in the amount of inflammation, of increased duration of the reaction, or of both of these manifestations, as compared with the alkali control. In none of these cases, in our opinion, was the difference sufficiently marked to be of practical diagnostic value.

The results shown in Table I may be summarized as follows:

TABLE II

SHOWING SUMMARY OF RESULTS OBTAINED ON SYPHILITIC AND NONSYPHILITIC PATIENTS WITH INTRADERMAL INJECTIONS OF TREPONEMA PALLIDA IN SALINE AND TREPONEMA PALLIDA IN ONE TWENTIETH NORMAL SODIUM HYDROXIDE SOLUTION. BASED ON TABLE I, WHICH SEE FOR LEGEND.

Syphilitics

Treponema in N/20 Sodium Hydroxide		*Treponema in Saline*	
N — 29	(74 per cent—Show no variation from control).	N — 23	(74 per cent—Show no variation from control).
CD — 5 C — 2 D — 2 W — 1	(26 per cent—Show some veriation from control).	CD — 4 C — 1 D — 2 W — 1	(26 per cent — Show some variation from control).

Nonsyphilitics

TABLE III

SHOWING SUMMARY OF RESULTS OBTAINED IN NONSYPHILITIC PATIENTS RECEIVING SIXTY GRS. POTASSIUM IODIDE DAILY, WITH INTRADERMAL INJECTIONS OF TREPONEMA PALLIDA IN SALINE AND TREPONEMA PALLIDA IN ONE TWENTIETH NORMAL SODIUM HYDROXIDE. BASED ON TABLE I, WHICH SEE FOR LEGEND.

Treponema in N/20 Sodium Hydroxide		*Treponema in saline*	
N — 22	(92 per cent—Show no variation from controls).	N — 22	(92 per cent—Show no variation from controls).
CD — 2 C — 0 D — 0 W — 0	(8 per cent—Show some variation from control).	CD — 2 C — 0 D — 0 W — 0	(8 per cent — Show some variation from control).

From Table II it will be seen that eight per cent. of nonsyphilitic cases in our series gave a reaction which might be considered as positive, whereas the definitely syphilitic patients gave only twenty-six per cent, of such positive reactions. This relatively large percentage of false positives when compared with such a relatively small percentage of true positives seems to demonstrate that the preparations used are unfit for diagnostic purposes.

The higher percentage of positives found in syphilitics is in keeping with the work of Kolmer, Smith, and others, who have found that the skin of a syphilitic patient is more sensitive to intracutaneous injections than is the skin of a normal individual.

The results obtained in the cases which had received potassium iodide appear to us to illustrate more clearly than ever that Sherrick's iodide reactions were due entirely to foreign proteins of the culture media, and in no part to the proteins of the culture media.

CONCLUSIONS

1. Intradermal injections of a saline suspension of Treponema pallida give so few positive and such contradictory skin reactions that it is not of use as a practical diagnostic test.

2. A suspension of Treponema pallida in one twentieth normal sodium hydroxide solution offers no advantages over a simple saline suspension of Treponema pallida for diagnostic purposes.

3. The administration of potassium iodide by mouth in doses of sixty grains daily does not affect the skin reactions produced by the intradermal injection of a suspension of Treponema pallida in either saline or one twentieth normal sodium hydroxide solution in nonsyphilitic individuals.

Gonorrheal Urethritis in the Male*

An Interpretation of the Disease Based Upon the Correlated Findings from Many Fields

P. S. PELOUZE, M.D.
Philadelphia

The history of gonorrhea is remarkable in a great many respects. It is neither equalled nor approached by that of any disease to which mankind is susceptible. It is a long study of separate problems that lack proper correlation of findings. There is no disease that compares with it in confusing the medical profession. The picture is simple but it has been terribly blurred and this blurring has worked fearful havoc upon the human race.

It seems almost useless to speak of the importance of this disease from a social and economic viewpoint but its dreadful toll of innocent women is far beyond the comprehension of a single mind. In them it has a direct and an indirect mortality that is appalling and a morbidity that would stagger society if it were known. This same society that has paid toll has been and is standing in its own sad light by a false modesty which brands it an "unspeakable disease," and yet, one hardly knows how to break down this barrier without doing more harm than good.

Being an unspeakable disease, it has attracted few of the best medical minds, particularly in this country, and its present outlook is bad. In the division of medical specialties it belongs to that branch that has of late graduated from genitourinary diseases to urology. They, who were once extremely interested in gonorrhea, now consider it somewhat beneath them and are thinking surgery of the urogenital tract. In their national meetings the question of gonorrhea is almost taboo, because the countless poorly thought out papers caused the move in selfprotection.

For these and other reasons the profession at large still remains at the mercy of any manufacturing chemist who can make and attractively advertise a gonococcicidal substance. Considering that these can range from distilled water up and can include anything but proper culture medium of just the right hydrogen ion concentration, it is obvious that the advertising must be of paramount importance.

Having spent countless years in following one particular trend of thought the curing of gonorrhea through the direct gonococcicidal action of some chemical despite the fact that it is directly contrary to the entire picture of the malady, is it not about time that we paused for breath? Should we not drop a few of the dreams of centuries and look in other directions for our answer? To do this we must correlate our laboratory and clinical knowledge and redigest it carefully. As this is done it is found possible to recast the picture to conform more nearly with the established facts that have seemed to point nowhere.

*From the Urological Department of the University of Pennsylvania.

PATHOLOGICAL CONSIDERATIONS

Before going further into the subject, however, let us briefly consider the pathological characteristics of the disease in the male for unless one understands these he is poorly prepared to grasp the remainder of the subject. The picture in its entirely is fairly complete and clearcut but it is scattered widely throughout medical literature and the importance of many of its smaller details are forced upon one only after years of thought and clinical experience.

The gonococcus is a germ with decided predilections for those environmental conditions that it considers ideal. Its natural habitat is mucous membrane lined with columnar or cuboidal epithelium (1-2-3). It can grow in the mucus covering squamous lined mucosa but it rarely penetrates its surface (4-22).

Having reached the columnar epithelium of the urogenital tract it quickly finds its way into the intercellular spaces and penetrates to the spaces of the (4-5) submucosa and at times along the trabeculæ of the corpus spongiosum. It does not enter the cells but forms minute colonies in the spaces between them where it grows with a degree of luxuriance dependent upon many factors (22), some of which will be considered later.

Being in its ideal habitat it completes its individual life cycle and sets up an inflammatory reaction that varies in different individuals. The immediate re-

sults of this irritant are a capillary engorgement with a consequent escape of serum and the diapedesis of polymorphonuclear leucocytes (2). The current of these is toward the urethral lumen so that, with the greatly increased production of mucus from secretory stimulation, there is set up a virtual tissue diarrhea. Such a condition, as it likewise occurs in other mucous membranes from other infections, is evidently Nature's best immediate means of combatting infections.

Contrary to the idea generally held upon this question the exuding fluids are evidently of greater value than the phagocytic action of the leucocytes. Also, their value is evidently solely mechanical at this stage for they have no bactericidal influences upon the gonococcus, which can be cultured after prolonged immersion in these fluids.

That phagocytosis is of secondary value is evident for several reasons which can be briefly stated as follows:

1. Phagocytosis is almost entirely confined to the urethral lumen and the superficial epithelium. It occurs in transit from the deeper layers but does not act upon the deeper placed bacteria which really perpetuate the disease (1-2-5-22).

2. The leucocytic cytase has no effect whatever upon the gonococcus. In fact, phagocytosis seems to preserve the gonococci and not to harm the leucocyte (7-8).

3. The germ will grow upon artificial culture medium just as well after as before phagocytosis.

4. It is therefore obvious that in gonorrhea the leucocyte bears about the same relation as the refuse wagon does to the housekeeper; gets it off the premises but it is still the gonococcus.

The result of this inflammatory reaction upon the surface epithelial cells is to loosen their attachments and reduce their nourishment to such an extent that many of them are shed off and replaced by a few or many layers of cells. The more superficial of these tend toward the squamous type and if the attack is prolonged they may ever keratinize to some extent (9). Also, in the prolonged and severe inflammatory reactions, there is more or less round cell infiltration which at times passes deeply into the corpus spongiosum. It is these infiltrations that later undergo fibrous tissue transformation and become the forerunners of stricture formation.

The infection finds its way into the many small mucous crypts and channels in association with the urethra (9-22). Here the pathological condition is much the same as in the free urethral mucosa except that the outlet is often blocked by swelling and drainage prevented. This naturally limits the escape of fluids and checks Nature's early efforts to remove the infection. The lumen of these occluded mucous structures fill with pus and epithelial debris (1-9). These accumulations of gonorrheal pus undergo disintegration both as to bacterial and cellular content and are of great importance in the present discussion.

The minuter pathology of Cowper's glands, the prostatic acini, seminal vesicles and epididymi differ in structure but not in kind.

RELEVANT FEATURES OF GONOCOCCAL GROWTH

Let us now turn to a consideration of certain cultural characteristics of the gonococcus and the effects of some of its products upon the body for they are of much importance in an understanding of the subject in hand. Our investigations in this regard are leading us more surely to the truth than has been realized and if we apply what we now know to the chain of evidence, we will find that it is a very valuable and suggestive link.

When the gonococcus is grown under artificial cultural conditions it follows a definite life cycle the stages of which are readily shortened or prolonged by very slight influences. There is a lag period which, in new cultures, ranges from twelve to twenty-four hours. The more suited the medium the shorter this period is in first cultures. In subcultures the lag period is gradually shortened, as would be expected.

Following this lag period there is a period of luxuriant growth the duration of which depends largely upon its nourishment. This is generally from twenty-four to seventy-two hours. After this a stage of autolysis sets in wherein the bacteria disintegrate and the culture becomes sterile. In new cultures and early subcultures one must not wait more than two or three days as a rule to subculture or he will lose his strain. Should the culture medium not be the most ideal, so that the germs from the start must struggle to survive, it will be found that bacteria of a more resistant type are generated. If, for instance, a tube of hydrocele agar and a tube of cornstarch agar, both of the same hydrogen ion concentration, be inoculated with the same strain of gonococci it will be found that they have one difference when examined under the microscope. At the end of four days those on hydrocele agar will only faintly take the stain showing that autolysis is well established and viability has ceased. Those from cornstarch agar at the end of six days will have almost reached the same stage, but in each field will be seen from two to a dozen larger and deeply staining diplococci that are subcultured with ease. Having been subcultured they seem able to stand more of an untoward nature than will subcultures from the original strain. This survival of the fittest may explain some of the vagaries of the disease in vivo, particularly the behavior of the urethritis in the presence of acute epididymitis.

If we take a dilute suspension of these dead gonococci and inject it into the normal urethra we will find that in from four to twelve hours there is set up a purulent, nonbacterial discharge that lasts from twenty-four to forty-eight hours and spontaneously subsides. The same thing, in perhaps a more marked degree, happens in the gonorrheal urethra but owing to the infection present it does not always entirely subside so promptly, though after two days there remains only slight activity above what was originally present (8-10-11-12-13).

With but a few faintly dissenting voices investigators are agreed that the gonococcus forms no exotoxin; that the gonotoxin is solely an endotoxin (15-16-17-18). There being nothing of the nature of an exotoxin in its life cycle, it cannot act as a tissue irritant until there is a liberation of its endotoxin by germ disintegration. It is likewise obvious that the liberated gonotoxin is highly bacteriotropic. In other words, it favors phagocytosis and is very highly irritating to the urethral mucosa, as has been previously mentioned. It is also much in evidence

that the gonotoxin is peculiar in that it does not desensitize laboratory animals upon repeated injection but, on the contrary, seems to sensitize them (19-20-21). In this respect the urethral mucosa is no exception, as is amply shown by our clinical experiences, for it becomes increasingly sensitive to very small quantities of the toxin.

From a clinical point of view gonorrhea presents many apparently contradictory features until we apply to them the results of our knowledge gathered from various fields. Among these may be mentioned the incubation period, the recrudescences of discharge following the imbibing of alcoholics, emptying of the contents of smaller mucous channels through manipulation of any type and sexual excitement or indulgence. More misleading still has been the cessation of urethral discharge with the incidence of acute epididymitis.

INCUBATION PERIOD

Bearing in mind the cultural life cycle of the gonococcus let us reason out what should happen when the germ is placed upon its most ideal habitat, the urethral mucosa. Under these circumstances, by allowing a rather short period of transit for the germ to reach the columnar cells we probably would find that the lag period was shorter than that upon artificial culture media. The period of luxuriant growth does not seem to be greatly altered, as evidenced by direct inoculation experiments (27-28-29), so that at about seventy-two hours from the time of inoculation autolysis should be well established. There is microscopical and abundant clinical proof that this is what really happens. It has been our custom to explain away the incubation period of the disease by citing the difficulty of transit of the germ from the meatus to the intercellular spaces of the columnar epithelium beyond the squamous lined fossa navicularis and to finish up by stating that "the presence of these bacteria set up a violent inflammatory reaction the product of which is a purulent urethral discharge."

It was shown years ago that at the end of thirty-eight hours after artificial urethral inoculation the gonococci had multiplied enormously and had penetrated into the deeper layers of the mucosa (22-23-24-25-26). These observations give us no clue to the conditions occurring at earlier periods but they do show us that the factors that we have used to explain the incubation period do not explain. Their requirements are complete at this period and probably much earlier and yet we must wait usually an equal time longer for the development of symptoms. (Clinical evidence is overwhelming against less than a forty-eight hour incubation time in new infections so that one can safely say that the establishment of the discharge at such early periods is always due to an exacerbation of the patient's own gonorrhea or from a shortly previous sexual contact.)

It, therefore, is obvious that the termination of our incubation period is not due directly to the presence of viable gonococci in the mucous membrane but to the liberation of endotoxin by destruction through autolysis at first and later by possible tissue processes.

To clarify this let us repeat. The transit of bacteria along the squamous epithelium of the fossa navicularis must be rather rapid for the incubation period in the male does not differ from that of the female where the infection commonly is engrafted primarily upon the columnar epithelium. The lag period should be but a short time and the period of luxuriant growth apparently is not greatly altered. Autolysis occurring throughout the various depths of the mucosa probably prompts a more ready inflammatory response than is the case when the bacterial toxin is injected into the urethral lumen. The four to twelve hours required for the appearance of a purulent discharge after the urethral injection of gonotoxin is probably greatly reduced.

With a bacterium so susceptible to time changes in its life cycle as is the gonococcus it is but natural that there should occur cases wherein the incubation period would be greatly prolonged. Culturally almost any variation can be produced; the lag period can be prolonged or shortened, as can be the stage preceding autolysis. It is clinically evident that even with the same strain of gonococci urethræ show the widest range of reaction to the disease so that the course of the infection depends upon the patient and not the particular strain. Briefly, gonorrhea is an individual disease and as differ the food and environment of the causal germ so differ the clinical manifestations.

THE CAUSES OF SYMPTOMS

If, therefore, we are correct in assuming that the objective and subjective symptoms of the disease are dependent upon the liberation of an endotoxin through autolysis or artificial bacteriolysis there should be much in the clinical course that is in accord with the contention. Let us see if this is the case. In doing so we must keep in mind several points regarding the time required for certain clinical responses to occur, viz. (8-10-11-12-13):

1. It requires from four to twelve hours for the establishment of a purulent discharge after the urethral injection of gonotoxin.

2. Such an inflammatory response lasts from twenty-four to forty-eight hours.

3. It almost invariably takes at least seventy-two hours for the establishment of an urethral discharge when gonococci are first inoculated directly upon the urethral mucous membrane.

It is also well to bear in mind that gonotoxin does not desensitize the urethral mucosa but, on the contrary, seems to make it definitely more sensitive so that much smaller quantities are required to bring about an inflammatory response.

As has been stated, pus retained in the smaller mucous channels undergoes a bacterial and cellular disintegration. It consequently should be rich in gonococcal toxins, as there is practically no absorption from these diseased glandular structures, and if liberated into the quiescent urethra should produce a purulent discharge within twelve hours if our contention is correct. Singularly enough, this is exactly what happens when one massages a gonorrheal prostate or opens an urethral crypt by massaging it upon a sound. Equally significant is the fact that, despite the presence of gonococci, most of such recrudescences of discharge subside into comparative inactivity within forty-eight hours, as is the case with the response of the normal or gonorrheal urethra to the artificial introduction of gonotoxin.

It was shown years ago by Finger and others that

in artificial superinfection of a latent gonorrhea it always took "more than forty-eight hours" for the appearance of discharge after the inoculation of the germs directly to the urethral mucosa (27-28-29). In other words there was, even in the quiescent gonorrheal urethra, an incubation period at least four times as great as that required for the appearance of the discharge after digitally emptying a gonorrheal pocket rich in gonotoxin into its owner's urethra. This time element is also much in evidence in the study of epididymitis, for it is a fact easy to demonstrate that the acute symptoms begin usually within twelve hours of some definite clinical factor that causes the transference of gonorrheal products to this tubule. The same is true in involvement of the posterior urethra following some errors of treatment or indiscretion on the patient's part. In both of these complications the symptom responses are so immediate that they cannot be due to bacterial penetration of the mucosa and are obviously true toxin responses at the outset. The presence of gonococci in the second glass of urine during the first twenty-four hours of acute posterior urethritis does not void such a view because the viable gonococcus accompanies the toxin as it does in anterior flareups from the emptying of retained pus.

The gist of the argument is that we must abandon the thought that the discharge occasioned by untoward events during the course of gonorrhea are due to reinfection in quiescent mucous surfaces. As a matter of fact, superinfection with a homologous strain is not such an invariable possibility and could not cause a response within the twelve hours required for the former reaction (29-30).

The recurrences of urethral discharge following sexual indulgence or excitement differ in no way from those due to the digital emptying of retained pus and are probably due to either pressure evacuation or the sudden increase of glandular activity that is physiological to this state.

The reactions following the drinking of alcoholics may be due to the same causes or may be dependent upon a sudden destruction of bacteria in the deeper tissues with a consequent liberation of their toxins. Considering that they follow the same clinical lines as the foregoing, the supposition is at least warranted.[1]

OTHER TISSUE RESPONSES

If we keep in mind the ground covered and think of each little intercellular collection of gonococci as a culture it is not hard to follow it through its various vicissitudes.

Despite the fact that this tiny culture has reached its ideal habitat it is the victim of much that is inimical to its longevity and, unless it is fortunate enough to have reached the submucosa of one of the smaller mucous channels, its career is generally not a long one. There are at least four processes against which it must contend. It must, to live long, survive the bacteriolytical and bacteriostatical powers of the tissue fluids, it must hang on against a virtual tissue diarrhea toward the free surface of the mucosa and it must escape the phagocytic action of the polymorphonuclear leucocytes.

Bacteriolysis and bacteriostasis are, in a large sense, individual and are what we call resistance. They are undoubtedly the main factors in the cure of gonorrhea and not our injected antiseptics and we help in the cure only in so far as we aid them.

The tissue diarrhea is a constantly decreasing factor and the phagocyte is a scavenger and little else. It removes the bacteria on the surface and immediately beneath it but does not annoy the deeper lying ones that perpetuate the disease.

It is clinically evident that these four conditions work at their best only where free surface drainage is at its best. They are slight or practically nil if there is no opportunity for surface drainage such as is the case in blocked prostatic acini or urethral follicles. In these structures the gonococcus tenaciously hangs on long after the free surfaces of the urethral mucosa have rid themselves of infection.

Reasoning from these premises there must be, in the early stages of gonorrheal urethritis, rapid growth and rapid destruction of the gonococcus. In this it is probable that the production of gonococcal antibodies plays a minor part if any. It is much in evidence that this process is not an early one in the urethral mucosa and in some few patients is almost absent.

Upon the advent of an acute epididymal infection the serological studies show an enormous increase in antisubstances. These often are so potent as apparently to bring about a condition of practical bacteriostasis in the urethral infections so that the rapid growth and destruction suddenly ceases and the discharge subsides or disappears until such time as the lessened absorption from the epididymis causes the decrease in antibody formation and allows the growth to flourish again. At no time during the course of the epididymitis does the antibody formation reach a stage wherein it kills all of the urethral bacteria. It is more likely that the antagonistic reaction during this stage is merely one of bacteriostasis and that this action is not sufficiently prolonged or complete to entirely check the proliferation of gonococci, so that all of those present complete their life cycle and autolyze. It is likewise possible that, during this stage of comparative urethral quiescence, gonococcal viability is maintained through the development of more resistant elements as is seen under cultural conditions that are almost but not quite ideal, as has been previously mentioned.

In explanation of the clinical picture of the disease one is compelled to consider both bacteriostasis and bacteriolysis as conditions rather closely allied. From cultural experiences we know that very slight changes

[1]There is however another possible explanation of the processes whereby the urethral discharge increases after the drinking of alcohols which may also explain some of the other singular features of this disease. It has been experimentally shown that alcohol in quantity retards or checks phagocytosis (Rubin, Jr., *Infect. Dis.* 1904, 1, 425. Hamburger, cited by Kolmer, *Infection, Immunity and Specific Therapy* p. 130). It would seem that anything that checked phagocytosis in the sensitized urethral mucosa would subject its superficial layers to an increased amount of gonotoxin, particularly if it in any way increased bacterial destruction, as it is here that phagocytosis occurs in gonorrhea. It may be that phagocytosis is one of Nature's methods of protecting the epithelium from toxins. This function is in a measure suggested by the cited fact that the leucocyte preserves the germ from lysis for a much longer time than is required for its escape from the properly draining urethra.

Such a function would square well with much of our other evidence and may entitle phagocytosis to a greater praise than has been accorded it as a curative agent. On the other hand such a function may be a factor in the prolongation of the disease by preventing endotoxin liberation in quantities sufficient to stimulate earlier antibody formation. The fact that the urethral mucosa is a poor absorbing surface in health and worse in disease may likewise enter into this and throw the entire responsibility for such stimulation upon the smaller number of bacteria in the submucosa and beyond.

make for a slow, struggling growth and let them be ever so little more and the bacteria are quickly destroyed. With a bacterium so easily influenced by even the slightest changes in food it is not difficult to see how such changes could occur in the tissue fluids and their effects could range from a slight retardation of reproduction through the various changes to slow or rapid germ destruction.

Such is what we call resistance and upon its countless variations depend the vagaries of the disease. As this resistance increases or diminishes, so change the duration and manifestations of gonorrhea. There is no true immunity in the urethral mucosa; it is a territory ever open to invasion; an invasion in which the contending forces are usually so evenly matched that the struggle is seldom a short one. Each side has its periods of triumph but in the male, at least, the final outcome is almost sure to be the complete rout of the offending invaders.

SUMMARY

1. The general understanding of gonorrheal urethritis in the male is more blurred than any picture in medicine.

2. There is urgent need for a better interpretation of our known clinical and laboratory data, for we have followed more false and foolish trends in regard to this disease than any other common ailment.

3. No disease has equalled it in therapeutic will o' the wisps and volumes could be written upon the foolish things that have been done.

4. As we analyze carefully the available knowledge it is found possible to recast the picture to conform more nearly to things as they are. These newer interpretations also furnish us with a far better working basis for treatment.

5. The disease in the male tends to follow a more clearcut course than almost any other mucous membrane infection.

6. The pathological picture is quite complete and offers much argument against the generally accepted thought that, we cure the disease by the direct bacteriocidal action of our various forms of treatment.

7. It is obvious that the patient really cures his own gonorrhea and that we help only in so far as we encourage or stimulate his curative processes.

8. The manifestations of gonorrhea are true toxin responses and occur only upon the liberation of the bacterial endotoxins through gonococcal disintegration.

9. The incubation period therefore covers the periods of transit, tissue penetration, luxuriant growth, germ destruction and the time required for the suppurative responses after the toxin liberation.

10. A study of the time required for these responses shows that what we have called reinfections are merely the toxin responses of a sensitized mucous membrane. The time required for the evidences of reinfection is at least five times as great.

11. The exudation of serum and the hypersecretion of urethral seromucus are Nature's best early curative agents.

12. Phagocytosis is a grossly overrated process from a curative viewpoint. It is confined to the superficial epithelium and the urethral lumen, being practically nil in the more deeply placed gonococcal colonies.

13. The formation of tissue antisubstances is the body's chief means of curing the infection. This process is good where tissue drainage is at its best and almost nil where drainage is interfered with.

14. These antisubstances are rather slowly developed in most individuals. Their formation can be encouraged and with even more ease it can be entirely obliterated. They range from the feeblest inhibitors of gonococcal proliferation to rapid bacteriolysins.

15. A knowledge of these things, together with the fixed habits and tissue predilections of the infecting organism are essential if we would understand and properly treat one of mankind's worst scourges.

Perforation of the Gallbladder with Intraperitoneal Hemorrhage

Report of a Case

EDWARD G. WATERS, M.D.

Jersey City, N. J.

Rupture or perforation from within constitutes one of the few surgical emergencies of the gallbladder. It presents a picture difficult to diagnose, yet demanding early recognition and intervention. The condition is most frequently mistaken for perforated peptic ulcer and the correct diagnosis made when the bile tinged peritoneum or peritoneal exudate is seen. The symptoms of shock, hypochondriac pain, and physical signs of upper abdominal peritonitis almost invariably direct the surgeon's attention to the correct region.

The following case is reported for the unusual physical findings and the unique complication of intraperitoneal hemorrhage from ulceration of the cystic artery.

Case.—Mrs. M. D., a widow, white, aged sixty-three, was admitted to the Jersey City Hospital, January 17, 1925, complaining of severe abdominal pain most marked in the left lower quadrant. A satisfactory history was not obtainable on admission due to the patient's poor condition. It was subsequently learned that for ten years she had had intermittent attacks of socalled indigestion, manifested by gaseous belchings, acid regurgitations, nausea, and rarely severe epigastric pain and vomiting. These attacks occurred most often after meals. "Stomach

upsets" had been frequent for the past six months and she had lost fifty pounds in weight. Occasionally she experienced a dull pain above the umbilicus which rarely became severe.

Four days before admission the patient had severe generalized abdominal pain with associated nausea. She took several cathartic pills without result. She was awake all night with pain of sufficient severity to cause her to cry out, and had persistent nausea and vomiting. Her abdomen began to swell, and despite taking a heavy dose of castor oil, she had no bowel evacuation. Her condition remained the same until the day before admission, when her abdomen became more swollen and the vomiting more persistent, although the pain lessened. On January 17th, the patient became extremely weak, vomiting became black and odorous, and the patient was given medical attention for the first time when the ambulance was summoned. There was no history of chills, fever, or definite localization of pain.

Her history was otherwise irrelevant. She had had no severe illnesses or symptoms except shortness of breath on moderate exertion, with tachycardia. There were no familial diseases.

PHYSICAL EXAMINATION

Physical examination showed the patient in such severe pain that her attention could not be held. She was vomiting "coffeeground" fluid freely. Her body and extremities were covered with a cold sweat, and the rectal temperature was 99.0°. Her few remaining teeth were in poor condition and the gums soft and spongy. Cursory examination of the chest showed no abnormality, and except for a few moist râles at the base, the lungs were clear. The left heart border was eleven centimetres to the left of the midsternal line in the fifth space and a blowing systolic murmur was heard. The pulse rate was 140, and of fair quality. The abdomen was distended, especially in the left lower quadrant, where the generalized tenderness was most severe. A tympanitic note was present throughout the abdomen, except in the flanks, where there was dulness. There was no pigmentation about the umbilicus. There were no points of acute tenderness over the appendiceal, gallbladder, or epigastric regions, nor was there localized rigidity. Rectal examination revealed nothing except ballooning of the rectum. There was fullness in both fornices on vaginal examination. A white blood cell count was twenty thousand with eighty-five per cent. polymorphonuclears.

DIAGNOSIS

From the history, examination and data available, a tentative diagnosis of intestinal obstruction was made and immediate operation advised.

OPERATION

A left lower pararectus incision was made under ether anesthesia. The peritoneum was found discolored. On opening the abdomen a definite ileus was observed, but there was no great bowel distention. Free and clotted blood filled the abdomen and pelvis. The pelvic organs were normal except for senile changes. Palpation of the entire colon showed no growth or obstruction. The spleen was intact. Both kidneys were normal in location and contour. The stomach was normal. When the gallbladder was palpated, the exploring hand withdrew about ten faceted stones of varying size. The true condition was then recognized and the wound closed in layers, in the usual manner.

An upper right rectus incision was then made after the manner of Robson, and the gallbladder exposed. The liver was small and sclerotic. It was observed that there had been no attempt made by the omentum to wall off the ruptured gallbladder, and that the site of the rupture was not at the fundus.

The perforation was then sought and found at the neck, opposite the ampulla. Pressure on the gallbladder caused extrusion of blood and stones, and it was seen that the site of perforation included the cystic artery, which was still bleeding. The gallbladder was opened at the fundus, and about 200 stones of varying sizes removed. The common duct was not obstructed.

Because of the very poor condition of the patient, it was deemed best to terminate the operation, and an angled clamp was placed at the neck of the gallbladder below the site of rupture. Another was placed along its hepatic attachment to cut off the circulation and induce sloughing. A gauze pressure pack was then placed under the neck of the gallbladder and a cigarette drain run to the common duct. No pus had been seen in the abdomen. The wound was then closed in the usual manner.

POSTOPERATIVE COURSE

The patient was returned to the ward in poor condition and reacted slowly from the anesthetic. Free drainage of bile was present the following morning. She continued dangerously ill and pulmonary edema was present to a marked degree. Heart beats were feeble and the abdominal distention was marked.

Her condition remained very critical until January 21st, three days postoperative, when the pulmonary edema was overcome. The cigarette drain and clamps were removed, but the gauze pack left undisturbed. There was free bile stained drainage present, nonpurulent, but examination of a stool indicated that there was no obstruction in the common duct.

On the fifth day postoperative, the clips were removed from the lower abdominal incision and four inches of gauze packing were removed from the gallbladder region. The patient's condition was only fair, and a hypodermoclysis of 1000 c.c. of saline was given. On January 28th, all of the packing was removed and the next day all sutures were out. Her condition was quite satisfactory.

Convalescence continued uninterrupted, and on February 6th all drainage had ceased. On February 12th the wound was clean and dry, and on the 24th, the patient was discharged as cured.

PATHOLOGICAL REPORT

The pathological report on a piece of tissue taken at the operation was "chronic productive and acute hemorrhagic cholecystitis, and cholelithiasis."

644 West Side Avenue.

Differential Counting With the Counting Chamber

A. J. HINKLEMAN,
Oklahoma City, Oklahoma

In a preceding article (1) the history of differential counting by means of the counting chamber and my finding a satisfactory combined diluting fluid and differential stain, have been dealt with. In the series of articles to follow I will deal with the facts in detail that an extensive study of the blood picture of the diseases and pathological processes commonly met with in medical practice, such as I have found it with the hemocytometer, according to the technic I have already presented With the simplicity and accuracy thus obtained, I have been able to gather together much of the mass of adversity and uncertainty that long has existed about the differential count and bring out a number of new points that, it is my belief, will help materially in the direction of making the laboratory stand more alone in the diagnostic question.

PRESENT STATUS OF THE DIFFERENTIAL COUNT

Outside of a very limited number of well defined diseases and pathological processes, such as the leucemias, whooping cough, smallpox, bronchial asthma, tuberculosis and malaria, very little of diagnostic importance has ever been claimed for the differential count. In the broad field of infections and febrile conditions, manifested generally by a leucocytosis, or a rise of the white count, we have been taught to look upon this rise as being due principally to an absolute increase of the polymorphonuclear cells alone. While it is conceded (2) that other cells are also involved in increased counts, at times, little attempt has ever been made by authorities to classify those infections or conditions of which the increase represents more or less all of the cells usually represented in the blood and those of which the leucocytosis is strictly a polymorphonuclear increase. Furthermore, little classification that can be depended upon has ever been made of the low counts or the leucopenias, eosinophilias and lymphocytoses.

Such classification has been out of the question, because the slide method of differential counting has not furnished a ready means of accuracy (3) through which it has been possible to detect the necessary degree of increase of the different cells of the blood. One or two hundred cells per c.mm. above high normal is considerable of an increase for such cells as the lymphocytes and the eosinophiles. However, such an increase would not have much of a bearing upon the percentage scale commonly in use, in differential counting from stained films. It is very much the same problem as attempting to gauge the temperature with a thermometer with which it is only possible to register five or ten degree variations, or to weigh ounces upon a scale that registers only pounds.

WHAT THE HEMOCYTOMETER HAS REVEALED

The hemocytometer, however, has revealed to me that not only are all of the white cells commonly represented in the blood frequently increased in high counts following infection, but that they are specifically increased in such a manner that a classification can at least be made of those infections and pathological conditions, generally represented with a leucocytosis, into a class of which the polymorphonuclear cells alone are increased and a class of which the increase represents one or more of the other types as well.

With the possibility of this classification, all has been gained that is really necessary in most instances to enable the physician or surgeon to locate the seat of infection. This may seem rather a broad statement at first thought. However, in consideration of what either the physician or the surgeon can always reveal through his physical examination and inquiry into the clinical history, if he can be told that the trouble is not among the diseases or pathological conditions of this class of infections, but must be found among the other, there are very few instances in which he has not received all the information he needs.

CLASSIFICATION OF THE COMMON LEUCOCYTOSES

Just how the process of chemotaxis is involved in this is hard to say, but it seems that it is not so much the character of the infection, in most instances, that determines the nature of the leucocyte response, but rather the location of the infection. The toxines produced by the Bacillus typhosus in the intestinal tract produce the well known condition of a leucopenia; while subcutaneous injections of the same organism produces a leucocytosis. A staphylococcus infection of the skin produces an increase of all of the cells of the blood commonly present, including the eosinophiles, while the same infection in the form of abdominal peritonitis appendicitis or infection of the uterine cavity would be represented by an increase of the polymorphonuclear cells alone.

ABSOLUTE POLYMORPHONUCLEAR LEUCOCYTOSIS

It seems that sources of the body from which the route to the circulation is most direct and where the rule of an infection is to rise rapidly and a considerable amount of toxic material has the opportunity to be taken into the blood before there has been time for much associate secondary lymphatic involvement to take place, the leucocytosis will consist of an increase of the polymorphonuclear cells alone. The organs and tissues of the body of which this is most strikingly true consists of the abdominal peritoneum, the appendix and the intestinal tract, the uterine cavity and the pericardium. To a lesser extent may be added the pleural cavities, the gallbladder and bile ducts. Furthermore, the action of such severe poisons as bichloride of mercury and phenol and the toxins of tetanus, streptococci in the blood, eclampsia and uremia give rise to a striking polymorphonuclear leucocytosis. Again, direct and severe shock to the brain and nervous system, such as follow skull fracture, concussion of the brain and traumatic amputation of limbs, gives rise to a

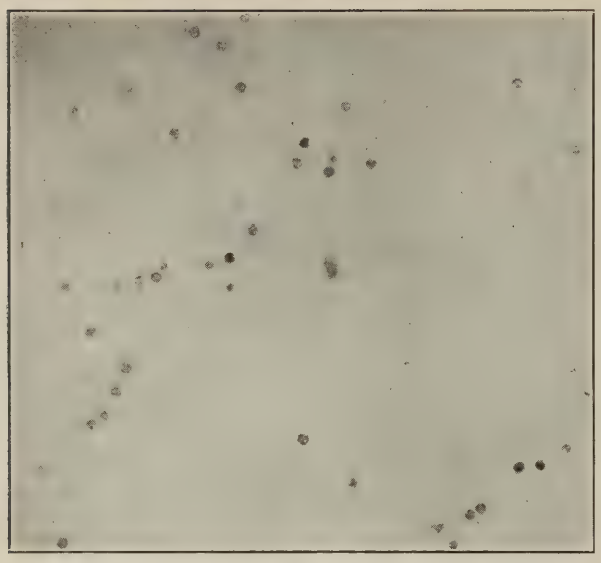

Fig. 1.—Low power field on counting chamber with combined differential stain and diluting fluid. Dark cells are eosinophiles and the light are polymorphonuclear leucocytes. Lymphocytes do not photograph.

Fig. 2.—High power field on counting chamber with combined differential stain and diluting fluid. Dark cells are eosinophiles, and the light are polymorphonuclear leucocytes. Lymphocytes do not photograph.

distinct increase of the polymorphonuclear cells alone. The following diseases and conditions may be expected to be represented by an absolute polymorphonuclear leucocytosis, if not complicated with conditions of the opposite classification.

Acute appendicitis and abdominal peritonitis, strangulated hernia, intestinal obstruction, intestinal and gastric perforation and ruptured ectopic pregnancy, infection of the uterine cavity, following abortion or retained membranes, acute infectious endocarditis, tetanus, bichloride of mercury and phenol poisoning, skull fracture, concussion of the brain and traumatic amputation of the limbs, eclampsia, uremia and, less definitely, acute pleurisy and cholecystitis in the absence of gallstones.

GENERAL LEUCOCYTOSIS

On the other hand, from sources of the body from which the route to the circulation is not so direct and the rule for an infection to rise less rapidly and associate secondary lymphatic involvement has a greater opportunity to proceed along with it, the leucocytosis will be more or less of a general type; involving the small and large lymphocytes as well as well as the polymorphonuclear cells and at times the eosinophiles. Such organs and tissues consists of the fallopian tubes, ovaries, epididymis, testicles and prostate gland in the male and the entire urinary tract, liver stomach and lungs. Among the tissues and other localities represented we have the skin, muscles, bones, lymphatic glands, tonsils and upper respiratory tract. Another factor that increases the number of lymphocytes and the eosinophiles rather than the polymorphonuclear cells is mechanical irritation to the sympathetic nervous system, such as adhesions, abdominal tumors, gallstones, renal calculi and stone in the bladder, foreign bodies, etc. The diseases and pathological conditions of which a general leucocytosis may be looked for may be numerated as follows:

Acute salpingitis and pelvic peritonitis, acute ovaritis, pyelitis and cystitis. In the male, besides the infections of the urinary tract, we have acute orchitis, epididymitis and prostatitis; also such infections as furunculosis and most other acute infections of the skin, rheumatism, osteomyelitis, liver abscesses, carcinoma of the internal organs, secondary syphilis, pneumonia, bronchitis asthmatic attacks, acute throat infections, including diphtheria and those associated with scarlet fever and measles.

It will be noted under the classification of a strict polymorphonuclear leucocytosis are included all of the most threatening and most directly fatal diseases and conditions, while under the classification of a general leucocytosis are included such conditions as are not so threatening and are slower toward a fatal termination. This may be taken as a good rule as to what to expect from the differential count.

CHRONIC INFECTIONS

Little claim has ever been made for the blood count at all in chronic infections by authorities and less is it depended upon generally among the physicians. However, it has been my experience in my work with the hemocytometer in differential counting, that while the total count may reach normal or subnormal figures, in the course of an infection, the differential count remains the same or unchanged as far as the original numerical relationship of the different types of cells are concerned. What is true of the differential count of the two classes of diseases and pathological conditions, in the acute stage, is also true of the same conditions in the chronic stage. Relatively the differential count remains the same, regardless of whether the total count is high, normal or subnormal.

RELATIVE POLYMORPHONUCLEAR LEUCOCYTOSIS

It is apparent that under stress of either severe or prolonged infection, in case of the diseases and conditions mentioned under the first classification of the differential count, the eosinophiles and the small lymphocytes are first to begin to fall in the course of failing leucocyte response and are also more affected finally than are the polymorphonuclear cells are. As a result of this, the relationship be-

tween the polymorphonuclear cells and the small lymphocytes are thrown out of balance and remains so as long as the pathology is operative. If the count is normal as to total number of leucocytes, the polymorphonuclear cells will nevertheless be found to be above normal absolute numbers and that there is a reduction of the absolute number of small lymphocytes. If the total count is subnormal, it will be found that the small lymphocytes have suffered a relatively greater reduction than the polymorphonuclear cells. Of the diseases and conditions of which such a differential count may be expected may be mentioned; failing leucocytosis of severe acute infections, such as gangrenous and ruptured appendix, gangrene of strangulated hernia, peritonitis, endocarditis and infection of the uterine cavity. As to chronicity, chronic appendicitis is practically the only condition in which a relative polymorphonuclear leucocytosis is found. In other parts and in diseases of such other organs as may give rise to such a count in chronicity, the process is usually fatal or has been relieved before this stage can be reached.

ABSOLUTE LYMPHOCYTOSIS

An absolute increase of the lymphocytes alone, as the primary response to infection, is rarely seen excepting in such diseases as lymphatic leucemia, smallpox, early stages of whooping cough,—in the later stages of this disease the polymorphonuclear cells become involved in the increase also—tuberculosis, some cases of syphilis before the outbreak of the secondaries, typhoid fever, influenza and malaria. On the other hand, an absolute lymphocytosis is frequently secondary to all cases of a primary general leucocytosis. It seems that in this classification of infections, the polymorphonuclear cells are more subject to failure of response than are the lymphocytes; consequently, under stress of severity or prolonged infection, all of the diseases and pathological conditions mentioned under the classification of a general leucocytosis may terminate with the differential count showing an absolute lymphocytosis.

RELATIVE LYMPHOCYTOSIS

This type of a differential count represents such counts as are normal as to total number of leucocytes, but of which there is nevertheless an increase of the absolute number of lymphocytes and the apparent normal count is due to an absolute decrease of the normal number of polymorphonuclear cells. Primarily, such a count may be found in typhoid fever, tuberculosis, influenza and malaria; secondarily, it may also be the terminal blood picture of all diseases and processes primarily represented with a general leucocytosis. It is simply a more advanced stage of the same process responsible for a secondary absolute lymphocytosis of the same conditions.

LEUCOPENIA

What is true of increased total counts is also true of decreased counts. The decrease may represent an absolute decrease of the polymorphonuclear cells alone with the lymphocytes remaining normal, or it may represent an absolute decrease of the lymphocytes with the number of polymorphonuclear cells remaining normal, and, like in the case of a general leucocytosis, the decrease may also involve all of the leucocytes commonly present. A classification may also be made of such counts into primary and secondary leucopenias depending upon whether or not the blood picture is that of the beginning of a process or the terminal.

PRIMARY LEUCOPENIA

As a rule a primary leucopenia is represented by an absolute decrease of the granular cells, but it may be represented by a decrease of the lymphocytes as well. In the case of typhoid fever the granular cells alone are involved, and the same is also true when found in tuberculosis and malaria. However, in severe cases of influenza both the granular cells and the lymphocytes may be involved and the same is also true of pernicious anemia.

SECONDARY LEUCOPENIA

Such blood pictures simply represent the terminal condition of either severity of infection or prolongation of the process and may apply to all of the diseases and pathological conditions mentioned under an absolute polymorphonuclear leucocytosis, and, likewise, to those mentioned under a general leucocytosis. In case the former was the primary blood picture, the leucopenia will be of the class of which the decrease represents the lymphocytes; while if the latter was the primary picture, the leucopenia will be of the class of which the decrease represents the granular cells or both. Clinically, a secondary leucopenia is not an encouraging condition, for it represents depletion or failure of the normal leucocyte response. In the more severe types of infection, it is the forerunner of fatality and in the less severe infections it means poor resistance and loss of the patient's reserve.

STATUS OF THE LARGE LYMPHOCYTES

Probably no other cell of the blood has stood so much in obscurity as to clinical significance as the large lymphocyte. It is normally present to the extent of fairly constant absolute numbers and may be found in increased numbers in every form of acute and chronic infection, but, excepting in such diseases as the leucemias, smallpox, whooping cough and malaria, with little regularity in any infection. Through what I have observed with the counting chamber, however, I have been able to gather a number of facts about this cell that I believe will shed some definite light upon its clinical significance. Through closely observing it in hemocytometer counts, over a period of five years, both in the hospital and in my own laboratory, it has been my experience that the large lymphocytes increase in a definite manner in response either to severity of infection or to chronicity. The rise of the normal absolute number of these cells in the blood invariably points to a beginning break or failure of the normal leucocyte response, either under severity or prolonged action of toxins or specificity.

This accounts for the irregularity of its increased numbers in the blood in any specific disease or pathological process, excepting those mentioned above; for the point at which the characteristic break in the normal leucocyte response, in the course of infection, is never the same in different individuals and is bound to be considerably varied also for a great many other reasons.

(To be concluded)

The Sanitary, Medical, Social and Moral Aspects of Birth Control*

S. ADOLPHUS KNOPF, M.D.
New York

Perhaps I should apologize for appearing before a purely medical audience to discuss a subject which would most likely be better treated by a specialist in diseases of women, an expert sanitarian, or a political economist. I know that not a few of my colleagues who honor me by their friendship, have often wondered at my interest in this as yet unpopular subject, and those familiar with my past work have asked themselves whether I have not enough to do in helping to prevent the spread of tuberculosis and treating the many unfortunate sufferers from this disease. I can only reply that it is through more than a quarter of a century's practice among these very sufferers from tuberculosis, the rich and the poor, in palatial homes and humble cottages, in dark and dreary tenements and overcrowded hospitals, that I have become convinced of the danger to individual and public health from thoughtless procreation, and last but not least of its utter immorality. And most of my experience has been limited to this one disease of the masses—tuberculosis—only.

The tears and sufferings I have witnessed when I have had to decline help because it was too late to prevent, the despair of the poor, frail mother at the prospect of another inevitable confinement, and later the sight of a puny baby destined to disease, poverty, and misery, has made me take the stand I am taking today.

The prevention of conception in a tuberculous mother actively ill, is advised today with, I think, few exceptions, by all tuberculosis workers, and it is my firm conviction that its practice has had its part in the constantly falling death rate from this disease during the last twenty-five years.

The importance of birth control considered in its sanitary, medical, moral, social, and economic aspects, is coming to be more appreciated, and wise laws concerning it should be helpful to the physician in his high calling to keep the mind and body of his patients in the best possible condition. The laws enacted in some states, however, which forbid giving contraceptive information even by physicians, cannot well be called wise and sanitary for neither sanitation nor medical science is furthered thereby. If these laws did not exist, I venture to say that we would have less infectious diseases, particularly venereal diseases; we would have less tuberculosis, and less diseases among children; for birth control, judiciously exercised, as has been demonstrated in other countries (Holland, New Zealand, and Australia), would lessen congestion and overcrowding. Families would be smaller and the breadwinner of the family could provide better care, better food, and better hygienic conditions in general for fewer children.

An illustration may be taken from my personal experience. In all my private cases, when taking the history of a patient, I have made it a practice for years not only to ask about the hygienic conditions—whether he has his own bed and his own room, whether there are any and how many windows in his bedroom, whether the windows lead to an airshaft or to an open street, etc.—but I ask also how many brothers and sisters he has or has had, and whether he is the first, second, third, sixth, eighth, or tenth child. Almost invariably in a large family it is one of the later born who contracts tuberculosis. The physiological reasons for this are doubtless the reduced vigor of elderly parents and the worn out condition of the woman after many previous pregnancies. She gives to the later child a heritage of physiological poverty which makes it less resistant to infectious diseases, and particularly to tuberculosis. But perhaps the most important reason for the later born children contracting tuberculosis more readily lies in the fact that with the increase of the family the father's earnings are rarely correspondingly increased. The results are overcrowded quarters, less good food and less warm clothing in severe seasons; and the mother, as already stated, worn out by many pregnancies, cannot bestow upon the later born children that care and supervision she gave to the first born.

How would the teaching of judicious birth control affect the unmarried population? I mean the young man and woman who would willingly enter wedlock were it not for the fear of having too many children. I believe there are hundreds of young men and women, physically and morally strong, who would gladly marry if they knew that they could restrict their family to such an extent as to raise a few children well. But their fear of a large family prevents conjugal happiness to which they are entitled and *ipso facto* prevents the procreation of a better and stronger man and womanhood. The woman sometimes withers away in lonely maidenhood and the man, whose sexual instincts are often so strong that he cannot refrain, seeks relief in association with the unfortunate and often diseased sisters called prostitutes. The result is a propagation of venereal diseases with all their dire consequences. These involve sterility, physical and mental suffering in the man, or sterility in both man and woman, and according to the severity of infection, pelvic disorders, abortion, premature labor, a dead child or one lastingly tainted with disease.

At times, disease does not enter as a factor in the tragedy, but the result is a girl mother and a blasted life, for our double standard of morality recognizes the so-called sin only in our sisters, not in ourselves. Of her, compassionate tongues say she loved not wisely but too well; of him nothing is said at all. He is spotless and virtuous in the eyes of the world and can go through life as if he had never sinned or been responsible for a ruined life or two.

In anticipation of some criticism by well meaning laymen and clergymen I may say right here what I have often said before regarding the prevention of

*Address, part of which was delivered by invitation at a Symposium of Birth Control before the Yorkville Medical Society, October 19, 1925, and read in full before the Medical Association of the Greater City of New York, December 21, 1925.

venereal diseases, illegitimate births, etc. I absolutely agree with those who believe that selfcontrol is the best possible, cleanest and purest preventative. But while this may be easy and possible for some, it is not so for everybody, and our psychologists and psychiatrists are not in full accord about the wisdom of total abstinence from sexual intercourse in full grown men and women. I am not going to discuss this question here, but wish only to state that from a purely sanitary point of view, teaching young couples desirous to marry, the means of contraception, to which they may resort until they are able to support a few children well, would cause a marked diminution in venereal diseases and result in many more happy and successful marriages; not necessarily fewer but surely more well developed children physically, morally, and spiritually. I wish to emphasize morally and spiritually. Recently the warden of one of our largest prisons, after reading the above statement that in the larger families, particularly among the poorer classes, it was the later born child who contracted tuberculosis, expressed the opinion to me that a moral handicap might exist among the later born offenders. The supernumerous youngsters, particularly in the families of the poor, have less care, are less supervised by the overworked mother than the first born and in a sense are often abandoned to the street and to the gang.

In an interesting address, The Unwanted Child Comes Before the Court, by Dr. Van Waters, delivered before the Sixth International Neo-Malthusian Congress, March, 1925 (1), we read the following significant words: "Deliquency in young children is a symptom of deep distress; delinquent children are often unwanted children."

Sanitation means prevention of disease and untimely death. The knowledge of contraceptive measures would be the saving of the lives of thousands of poor mothers who in their desperate efforts to get rid of an unborn and unwanted child, resort to violent and dangerous means to attain this end. The report of a Special Committee on Criminal Abortions, quoted in the *Textbook of Legal Medicine and Toxicology* (Peterson and Haines, Vol. II, page 92), states that "one third of all pregnancies throughout the country end in abortions. This is estimated at not less than one hundred thousand yearly. A large number of these are criminal abortions from which the committee estimated that six thousand women die yearly."

We must of course make it plain right here that there exists a sharp line of demarcation between abortion and the prevention of conception. Dr. Ira S. Wile, when discussing the subject before the American Public Health Association (2), has well said: "The former is life destroying, the latter is life saving. The interruption of pregnancy to destroy a developing ovum entails physical hazards to the woman which often adds to the mortality rate. At the same time, this is the destruction of life, feticide, literally speaking, infanticide." Knowledge of contraception, imparted to the married woman, may not only preserve her own life and health, or prevent her from invalidism, but it is most likely also to add to the happiness and social and economic wellbeing of the family.

Among the diseases which may be aggravated or cause death in case of an additional childbirth, we must mention serious heart disease, diabetes, tuberculosis, syphilis, leucemia, hemophilia, general debility, epilepsy, the various psychoses, and uncontrollable vomiting, particularly when as a result of previous pregnancy a therapeutic abortion had been performed. Prevention of conception should be imperative in a case of a malformed pelvis when a Cæsarean section or craniotomy had been performed because of previous pregnancy. All this comes under the heading of preventive medicine.

Scientific prevention of conception has not been, and to the best of my knowledge is not now, taught even in our best medical schools, with the exception of the Medical Department of Johns Hopkins University, which has offered each year for the last three years one comprehensive lecture on birth control to a group of elective students.

Concerning the great lack of study of contraceptive methods, I like to quote the following information given by Dr. Robert L. Dickinson: "Finding that no organization was willing to make the study concerning contraceptives, a selfconstituted group, chiefly made up of well known New York physicians, started, in March, 1923, an inquiry into birth control, sterility, and of sterilization of those whose progeny constitute a social menace. Researches are under way looking toward determination of long term methods that do not present the handicaps of present measures." Dr. Dickinson is the secretary of the Committee on Maternal Health with offices at 370 Seventh Avenue, New York City. Its first report has already appeared (3). I have the assurance that our powerful American Medical Association will be helpful in spreading such knowledge as may be obtained through the work of this committee. In a personal letter recently received, the editor of the *Journal A. M. A.* said: "We hope from time to time to give attention to original investigations or reports of new studies in the field of contraception." It is to be hoped that as a result of the studies of the Committee on Maternal Health new special birth control clinics, where physicians can receive proper instruction, will be established.

The opponents of birth control claim that disease and misery, mental and physical suffering, are far greater when conception is interfered with than when Nature is allowed to run its course. To this let me answer that it has been proved that the physiological effect of voluntary parenthood is not only less disease in general and less venereal disease in particular, but a stronger and physically and morally better man and womanhood. In Holland, where the medical and legal professions have openly approved and helped to extend artificial restriction of the birth rate, the health of the people at large, as shown by its general deathrate, has improved faster than in any other country in the world. Although there are no official birth control clinics in Holland, physicians are allowed, by royal decree, to teach judicious and ethical means of contraception. At a recent eugenics congress it was stated that the stature of the Dutch people had increased more rapidly than in any other country—the increase being no less than four inches within the last fifty years. According to the Official Statistical Year Book of the Netherlands, the proportion of the young men drawn for the army over

five feet seven inches in height has increased from twenty-four and a half to forty-seven and a half per cent. since 1865, while the proportion below five feet two and a half inches in height has fallen from twenty-five per cent. to under eight per cent. Concomitant with this increase in stature, the deathrate has decreased more rapidly than the birthrate and there is still a normal increase in population. The families of the poor have fewer but better children, and what is most interesting to observe is that the families of the well to do in that country are not nearly as small as in other countries.

If we contrast Holland with some of the overpopulated countries, we have a graphic picture of the effect on the labor situation. Wherever there is excess of population there is unemployment, be this in Asia, Europe, or America. The standard of living and sanitary environment of the laborer are lowest where labor is cheapest and laborers abound. It reaches its lowest standard in India and China. I have never visited China but have seen the Chinatowns in many of our cities in the West and in the East, and if the lives of these people here are an example of what sanitation is in China, I do not wonder at what an epidemic of any infectious disease means in that country.

It is surprising that in view of our present knowledge of the causes of disease, the danger of congestion, of underfeeding, and the other causes of social misery in men and women, caused by an overpopulation, that there are so relatively few advocates of birth control, which should perhaps be more correctly called conception control, in the medical profession. In fact, among many of our colleagues there exists an outspoken hostility to the movement. They oppose birth control on ethical and moral grounds or believe that there is no danger of overpopulation. Yet I might quote many distinguished American and English clergymen of nearly all the Christian and Hebrew denominations who do not consider judicious birth control immoral, but not to lengthen this communication too much, I will merely give the opinions of two distinguished representatives of the Protestant and Hebrew persuasions.

As recently as June 1, 1925, the Rt. Rev. Bishop Barnes, of Birmingham, England, when preaching before the Royal Institute of Public Health, advocated birth control in the following words: "Human welfare is now menaced by human fecundity. Vast masses are deprived of the uncramped freedom necessary for healthy existence. The change from large to small families is not to be impatiently condemned. Victories in medicine and hygiene may be disastrous for public welfare unless the desire for many children, which is natural and until recently laudable, is held in check."

The Rev. Stephen S. Wise, the senior Rabbi of the Free Synagogue of New York, upon direct inquiry for his opinion on birth control, wrote me as follows: "Viewed traditionally, birth control can hardly be said to be sanctioned by the teachings of the Jewish religion. The position of those of us rabbis who favor birth control grows out of our conviction that it is our duty and our right as teachers in Israel to take a position touching the problem of birth control, because since the Bible canon and rabbinical code were closed we have come to have new light upon some of the most important problems of life. I accept the evolutionary hypothesis and as a collateral implication I accept the viewpoint that birth control is a necessary factor in present day life. The business of religion is to improve man and to better the social order which is his background. I accept the teaching of the scientists that in order that there may be a better, finer race, and in order that the social order may be increasingly livable, it is become necessary to accept birth control as a factor in the social life of man. As a Jew, I feel particularly justified in taking this position because the religion of Israel holds human life to be sacred. The sacramental attitude toward life appears to me not to dictate that there shall be an illimitable and unchecked generation of life, but that humans shall will to give life to children only when they are fitted to be the bearers of life and to give to children such background as gives the fullest chance of life worth living."

In addition to these strong statements by high ecclesiastical authorities I will give an abstract from an editorial in the *Christian Century* of August 27th, perhaps one of the most widely read of American religious journals: "The more intelligent classes already practice birth control, while the less intelligent, who lack the knowledge to restrict their birth, are breeding so prolifically that they imperil the general standards of human excellence of the race. The welfare of society therefore demands that all classes be placed in command of the same information, so that restriction of births may be fairly equal in all classes."

As physicians, sanitarians, and American citizens, do we not all approve of more children among our healthiest, most intellectual, and most moral stock, where there are at present altogether too few? There must be birth release as well as birth control, but to those who cannot see that there is nevertheless danger of overpopulation, I recommend the study of the works of Cox (4), Fairchild (5), Malthus (6), Paul (7), Pearl (8), and Wolfe (9). The last named, Professor Wolfe of the University of Ohio, declared before the American Statistical Association last December that "unless the birth rate is retarded, a few generations at most will see it at the saturation point." Professor Fairchild, after a survey of conditions in both the old world and the new, estimates the population for America as 550,000,000 at the end of the twentieth century, and for the middle of the next century, as many people as there are now on the entire globe.

Raymond Pearl, in his latest book, *The Biology of Population Growth,* while speaking hopefully of that as yet little understood biological phenomenon, "adaptation," concludes by saying: "We can only dimly envisage a small fraction of the changes in the mode of human existence which population pressure will entail. But that these responses to environmental forces will be generally adaptive seems to me certain. They will somehow or other conduce to wellbeing and happiness. Birth control would seem to be a case in point. It is an intelligent adaptive response to an evironmental force, population pressure. It is an attempt to slow the rate of population growth and thereby maintain the level of living standards. It will become more and more widespread."

Indifference or hostility to these questions on the

part of physicians and sanitarians will not further the welfare of the nation. Fortunately, there are always a few brave men among the leaders of the American medical profession who are not afraid to deal frankly with these vital issues. Among the past presidents of our American Medical Association, the late Professor A. Jacobi was, and Professor Charles A. L. Reed and Professor William Allen Pusey are, in favor of birth control. You are all familiar with the latter's wonderful essay on Medicine's Responsibility in the Birth Control Movement (10). From it I will quote that chivalrous sentence referring to the fact that while birth control is truly a man's problem, it is above all a woman's problem: "It is woman that bears the penalties in injuiry, disease, death, and mental torture that are involved in childbirth. She has a right to know how she can intelligently—not crudely and dangerously—control her sexual life. And she is justified by the highest considerations in fighting vigorously and persistently until she has this right granted to her."

The woman of today is demanding the right to use her God given intelligence to decide the number of her offspring and regulate the time of their arrival. No less an authority than Dr. Alexis Carrel, of the Rockefeller Institute, winner of the Nobel Prize for his scientific researches, strongly emphasizes the advantage of quality over quantity in the human race and the utilization of man's brain power for more intensive study toward this end. In a recent brilliantly written article for *The Scientific Monthly* (11) under the title The Future Progress of Medicine, he says: "The spiritual progress of man could be greatly promoted by a scientific knowledge of the physicochemical phenomena which take place within the brain cells. Instead of merely increasing the number of human beings, we could increase their quality. The progress of medicine, understood in this manner, would be the most important factor in the development of civilization."

Alas, laws forbidding a married couple to use their brains in the interest of voluntary parenthood, instead of blind procreation, are still in force in our own and many other states. On the other hand, there is no restriction of the procreation of the unfit. The diseased in body and mind are allowed to reproduce *ad libitum*. The progeny of domestic animals, the horse, the cow, the hog, and others, are controlled by man's intelligence but human beings are indiscriminately procreated.

My late friend and teacher, Dr. Hermann M. Biggs, whom we may justly consider to have been one of the greatest sanitary authorities of our time, prior to the dismissal of the case by Judge Dayton of the Federal Court, against Mrs. Sanger for sending information about birth control through the mail, gave to the press the following statement: "I am strongly of the opinion that the present laws in regard to the governing of infant control are unwise and should be revised. There can be no question in the mind of any one familiar with the facts that the unrestricted propagation of the mentally and physically unfit, as legally encouraged at the present time, is coming to be a serious menace to civilization and constitutes a great drain on our economic resources."

Mrs. Margaret Sanger, the woman who suffered imprisonment and persecution for her advocacy of birth control in its medical as well as sociological aspects, receives an average of sixty thousand letters annually from mothers in distress. Some are from virtually destitute mothers who have too many children already and fear that there will not be enough to feed a new arrival; others are from mothers afflicted with diseases of all kinds, feeling intuitively that an additional pregnancy will aggravate their condition. Federal and State laws make Mrs. Sanger virtually powerless to help directly, except in the comparatively few cases which come to the clinic and in which reason for advice is based on actual disease or when an additional pregnancy would endanger life.

This clinic is maintained by the N. Y. Branch of the American Birth Control League and was founded by Mrs. Sanger. It is under the supervision of two physicians in good standing. No advice is given and no contraceptive help is extended to the healthy married woman or a single woman who desires to marry but for economic reasons wishes to postpone motherhood. Such advice on purely sociological grounds cannot as yet be given without violation of the law. The clinic is conducted on strictly ethical principles, but besides aiding the diseased mothers in the prevention of further childbirths, the institution has another purpose. Just as there exist among the well to do, women eager for children but who are apparently sterile and who by surgical and medical means can be cured of their sterility, so one finds among the poor many seemingly sterile women who are eager for motherhood. In such a clinic they may obtain the same advice and help free of charge as is given to the well to do by expensive specialists, and they may thus have their hearts' desire for a child fulfilled. Physicians in good standing are admitted to the New York clinic for instruction. In a letter addressed to the editor of the *Journal of the American Medical Association* (Oct. 10, 1925), Dr. Robert L. Dickinson, of New York, referring to the work of the American Birth Control League and that of the Committee on Maternal Health, mentions the fact that seven thousand physicians have applied to the League for information on contraceptives. It is thus evident that there is an urgent need of scientifically and ethically conducted birth control clinics in the interest of suffering mothers and also of physicians willing but evidently not sufficiently well instructed to be helpful to them. May our municipal, state, and federal legislators and their advisers in sanitary and medical matters soon awake to the crying need of modifying the existing absurd laws which impede the establishment of these clinics. Because of the incongruity of the postal law which makes all discussions on contraceptive technic and results unmailable, the American Gynecological Society was prompted last May to recommend the following amendment: "Standard medical and scientific journals and reprints therefrom and standard medical works which contain information with reference to the prevention of conception are not nonmailable under this section."

Many people oppose birth control on religious grounds, maintaining that we must not interfere with the laws of nature, which are the laws of God. In that case we must not advocate peace, use intensive cultivation, construct lightning rods, prevent small-

pox or typhoid by vaccination, nor give our children antidiphtheritic serum and not operate for cleft palate or other congenital deformities. We must allow a pus filled appendix or an extra uterine pregnancy to take their natural course, which means death. We must never perform Cæsarean section but allow mother and child to die rather than prevent nature taking its course. The prematurely born child must be left to cold nature and not be put in an incubator with artificial warmth to preserve its existence. If we must not interfere with nature at all, we are not even entitled to artificial teeth which prolong our lives, enabling us to masticate our food properly. In many instances it is our duty to interfere with nature's course, not only in our own interest and for our preservation, comfort and happiness, but at the same time see that all those blessings may also be bestowed upon future generations.

In conclusion, let me touch on a subject which is somewhat difficult to classify but which, I believe, nevertheless belongs to preventive medicine for it relates to the prevention of a pathological mental condition in many married men and women, particularly in the women, which for want of a better name we call anxiety neurosis. It is the fear in the minds of the married couple who already have enough children of the arrival of more little mouths to feed, that causes this condition. Our relatively new science of psychoanalysis has traced to this fear many a severe nervous and mental condition, resulting even in typical insanity. At times there is added to this neurosis the nervous strain coming from an endeavor to repress the sex urge, which makes this mental suffering even more serious. Yet, all married men and women who are in the prime of life are entitled to the fullest conjugal happiness. With the knowledge of birth control they may enjoy this; lacking this knowledge, there are cases where the fear of too frequent childbirths on the part of the already overburdened wife, makes her frigid to the husband's embraces and disastrous consequences ensue. The ignorance concerning contraceptive measures results in wrecking what would have been a truly happy marriage with a few lovable and healthy children.

It has been said that a general knowledge of birth control would lower the moral standard of the unmarried. In answer to this, I may say that a good many people who are unmarried and are eager for illicit intercourse already know preventive measures; but the saving of thousands of lives, the bringing into this world of only wanted and welcome and not unwanted and unwelcome children, the many more happy married young couples, the prevention of venereal and other infectious diseases, would make up a thousand fold for the isolated cases where resort was had to contraceptive measures by those who, according to our standard of morality, should not be entitled to them.

We look upon our presidents of the American Medical Association, who are elected by approximately ninety thousand American physicians, as the standard bearers of all that is scientifically, ethically, and morally sound in medicine; so, if we subscribe to what Dr. Pusey has said concerning the morality and ethics of birth control, we cannot go far wrong. This is what he said in the above mentioned address: "Adequate and satisfactory methods of birth control and widespread knowledge of them, would not only conduce to human happiness and social betterment but would be invaluable influences in favor of sexual morality. They would indeed promote morality in its broadest and best sense."

I referred to the anxiety neurosis created in many married couples because of lack of knowledge how to prevent an undesired conception. In the name of all that is holy and sacred to all physicians, who are supposed to help prevent diseases of mind, heart, body, and soul, can we take upon us the responsibility of denying to such couples the knowledge which will render them healthy and happy and prevent a sure catastrophe? And yet, there are laws in some States of the Union which would punish us for doing so.

Concerning the injustice of and the harm done by such laws, we will finally quote one of our most distinguished authorities on psychiatry, Adolf Meyer of Johns Hopkins (12). Discussing what he calls "The Obligation of Procreative Hygiene" and avoiding all extreme statements concerning the propaganda of scientific and judicious voluntary parenthood, he concludes by saying: "We are urging nothing more than this: that physicians be protected against unjustified prosecution to which they are liable in some States, when they follow their medical conscience in advising married couples who need it with regard to the wisest and sanest adjustment of married life so as to avoid unjustified accumulations of pregnancy and the hazards of any probable ill health of the potential parents and progeny."

Because, some years ago, Anthony Comstock, a well meaning but misguided and fanatical reformer, was instrumental in causing federal and state laws to be enacted which hinder the physician in his duty toward suffering women and forbid him to prevent physically and mentally unfit children from coming into the world to constitute not only a burden but a danger to the community, are we as physicians, entrusted with the physical and mental welfare of the citizens of this great country, to remain idle and indifferent in face of the absurdity of such laws? Not only as sanitarians and physicians but also as men and women, lovers of mankind, we must be in favor of preventing overpopulation which we know has been in the past the cause of aggressive wars, pestilences, and untold human sufferings. Let us arise and demand the revocation of such laws which, by their very nature, prevent the United States from being the leader in human progress, world peace, happiness, and good will on earth.

Historical Medicine

The Treatment of Stricture of the Urethra in the Sixteenth Century

SIR D'ARCY POWER, K.B.E.

London

Perhaps the earliest essay on the treatment of urethral stricture in the male is that published by John Read in 1588. It is entitled *A Treatise of the Caruncle or Carnositie; growing in the yarde, or necke of the Bladder.* Read says that the author is unknown but that the manuscript was "given me by a gentleman being my patient of a certaine griefe, who being cured, in recompence of my good will, gaue it me, not knowing whether it were a translation out of any author, or a collection of some learned and skilful man."

The treatise begins: "Albeit, ulcers and sores are wont to rise upon divers occasions, not here at this time to be repeated, yet do they come no way more commonly than by the long continuance of the gonorrhea, if it be not orderly and perfectly cured. And of ulcers either neglected or else not well cured certain increasements and unnatural swellings of the flesh which we call caruncles or carnosities, are accustomed often times to proceed." From this it is clear that our predecessors looked upon stricture of the urethra as being due to a growth obstructing the lumen rather than as a narrowing of the passage.

"The signs and tokens of a caruncle either in the neck of the bladder, or in any other part of the urinary passage, are these:

1. A great difficulty or hardness in making of water, the which water having his course readily to the place affected, is stopped and stayed there so much that it cannot have his issue, in any other sort than dropping wise. And that also not without the great help and enforcement of ourselves.

2. And therefore such as are tormented with this disease, whiles they go about to make their water, are constrained in the meantime, at the same instant sometime to avoid their other excrements also.

3. And whiles they chance to do the act of generation, their nature stayeth in the middle way of his course. And being stayed destillethor trickleth from them so faintly, so coldly and with such small delectation and pleasure that, as touching generation, they may be judged unfortunate, and therein to lose but their labour. For it is impossible for the time that any man hath this disease, he should beget any issue.

4. Again when the patient maketh water, in the very water itself, something stayeth beside the caruncle, which cannot well be put forth or expelled, except the root of the yard be pressed hard with the patient's finger.

5. Moreover the urine itself in this case cometh not forth with a direct and straight course, but aslope and in crooked sort either on this side or else on that, yea and sometime it is divided as it were into two streams.

6. It chanceth also oftentimes that the urinary passage is so stopped and choked that the urine, being not able to use his ordinary course and issue, breaketh forth by other ways and in this case nature seeketh wonderful shifts to help herself, for I have known many that have made water between their codds, and some again have done it at their fundament, and other some, out by their flanks and parts called in Latin *Ingume.*

There are two ways of curing the caruncle. The one violent and not without danger, that putting in some instrument of tin or the like we should pull the caruncle up by the roots, in such sort that not only urine, but blood also itself, yea and gobbets also, and fragments of flesh, should be brought forth.

The other way is more gentle and easie, and without all danger, which is not done by violence or iron instruments, but by the operation and working of medicines, and this way the old writers did not know. If then we have a patient in this order troubled his body should be skilfully and sufficiently prepared and evacuated. And in this point the patient must altogether be directed and ruled by some discreet and learned physician. And this once being done then, take a fine tender Mallow stalke, or a smallage or parsley stalk, and anointing it with oil of sweet almonds tenderly and softly to make proof of the neck of the bladder, having good regard that, in no case, you provoke much or pain extremely. But if it chance to stick by the way, so that it either do bend, or offer to break, then it is to be drawen out againe forthwith, and a wax candle must be put in, and that of such bigness as the urinary conduit may easily receive. But for that it may be feared, lest if the candle should break within the yard, as in winter especially it may come to pass for the hardness of the wax, some portion thereof might get into the bladder and either scantily be gotten out again or else should anger and exasperate the parts already painful and exulcerated. Therefore it were to be wished that the candle were made of a strong kind of thread and not only of wax, but of wax and turpentine artificially mixed together. Our candle being thus made, when we have so rebated and blunted the end that it cannot hurt or gall, then we must anoint it with oil of sweet almonds and then something bending it towards the smaller end we must put it in oftentimes into the urinary conduit. And if we perceive once that the candle get beyond the caruncle, which is perceived by the rubbe or as it were a little jump by the way, and by the estimate of length of the portion that is gotten in, then may we think that one half of the cure is obtained.

If it shall fall out that the tumor shall be so hard and stubborn that it will not yiled and give place to the candle. Then may you make a probe or searcher of lead of the same length and bigness. Anointing it with the foresaid oil, so to use it. For lead is

not only an easier and mitigator of pain but also it hath the property and faculty of drying of ulcers. And besides that also, with his very weight it presseth them and causeth them something to stoop and shrink in.

The flesh may chance to be so hard and rebellious, that a leaden instrument shall not be able to master it neither, and then in that case, you must use a silver or a golden catheter or siring. And yet before we do use any such either of silver or gold, my counsel is that you do make trial again and again, by the forenamed means. For the use of this siring hath this discommodity, it being nothing pliant and flexible and hitting upon those most tender and sensible parts it causeth oftentimes great and terrible fluxes of blood, which doth discomfort both patient, chirurgion and physician also.

The patient while he is to be searched is to be placed in some convenient place, his face being upright, and the chirurgion standing on the right side and holding his yard in his left hand, let him put in and direct the instrument with his right hand, and when he is come to the neck of the bladder, then something bending down both yard and instrument, let him fair and softly force it forward into the bladder.

When ye have thus past the caruncles or got beyond them all along the urinary conduits, even to the bladder, then that instrument wherewith you have done the feat, whether it be a candle or the leaden searcher, or catheter must remain, and be left within for one whole day, and the patient must be enforced so to make his water—if the pain be not too intolerable. For by that means partly, by reason of the course of the urine partly by the instrument itself, the water passage will be enlarged and amplified. Your catheter or searcher of lead being drawnen forth after the long tarrying there, if by them your work be perfected so far forth, then must your candle be put in last of all, and suffered there to remain, till such time as it doth receive some print or mark by the compression of the caruncle, and that will be a good help to apply the medicine withall to work the cure. The candle being drawen out, it must be curiously looked upon and viewed, to espy in what part it seemeth to be printed in or compressed.

Since we cannot apply neither lint nor pledget unto ulcers which be hidden in the inner parts of the body, so as we might do if they were in the skin and outer parts, and therefore cannot conveniently apply any plaister either, therefore that commodity is supplied by the wax candle, for the medicine being put thereon, it doth lead it as it were with a line, to the place affected. But the candle must be something hollowed and prettily pared away in that place where the medicine must be placed. Lest if it bear out and be not even and equal, it cannot then get through to the place where the caruncle is.

Provided always, while these things be thus adoing, if any intolerable pain or unaccustomed shivering, or cold, or ague or any other grievous accident do chance to molest and torment the patient, straightways the candle is to be taken out, and the urinary conduit to be washed with goat's milk, or rose water wherein a little camphor is to be mingled, and so long, you must cease all other actions of chirurgery, till such time as all such accident and impediments be removed and taken away.

By these few notes and instructions, any skilful chirurgion may be able to judge and discern a caruncle; and be also sufficiently instructed, by the might and power of God to cure the same. Who as he is wont to punish mankind with innumerable diseases, to the end to abate his pride, and to make him know himself, so is he also accustomed to help and succour those who fly unto him for comfort, and do trust in his mercy."

Although the authorship is unknown the treatise bears all the marks of English surgery of the Tudor period. Its language is so idiomatic that I do not think it has been made to speak English from a foreign tongue. It is clearly the work of a surgeon who has had practical experience in the treatment of stricture of the urethra, for it is not likely otherwise that he would have warned his readers against the dangers of urethral fever. The employment of the candle in the treatment of stricture makes the bougie an older instrument than is generally supposed, whilst the terminal recommendations to God is more in the style of the fifteenth than of the sixteenth century.

What Did the Indians Know About Medicines and Healing Treatments?

LESTER G. HERBERT
Auburn, N. Y.

Just how much did the North American Indian know about drugs and medicines? Were the treatments offered by the ancient medicine men wholly made up of superstition and fetishes, or did the aboriginal inhabitants of this continent have some practical knowledge of healing herbs and animal and mineral drugs? If so, how much did they know, and how exact was their knowledge?

They certainly were not skilled in laboratory practices, nor in accurate information as to therapeutic values, doses, of active principles, and other knowledge which we consider essential today. Occasionally we see a remedy even now promoted on the plea that it embodies an original and valuable formula known to Indian people who used it with success for the healing of various diseases.

Before the misbranding legislation became operative, there was much more of this class of socalled Indian remedies on the market, many of which, without doubt, never were used or originated in any way, form or shape by Indians.

Many of the older people can remember the typical

Indian doctor with long hair, broadbrimmed sombrero, longtailed coat, and a watch chain as big as your thumb, draped across the front of his vest, who appeared periodically, selling Indian medicines from the rear of a neatly painted wagon, drawn by a pair of high steppers, always groomed until they shone like a bottle. That Indian medicine man always was a glib talker. Sometimes he had a little Indian blood, and sometimes he didn't have any, but his makeup was effective. Frequently he was accompanied by an attraction in the form of a singer or a sleight of hand man, or a story teller who helped to get and to entertain the crowd.

An amusing character based on the old time Indian medicine man is to be met in the modern novel, *Oh, Professor, How Could You,* and if anyone wants a good laugh and a chance to forget his own cares, this novel by Wilson will satisfy.

However, because there was so much white man fake in relation to Indian medicines, they fell into disrepute, in the course of time, and came to be looked upon by most legitimate, trained druggists as mere "belly wash."

Just the same, the Indians did have an amazing knowledge of herbs and some other supplies, and their pharmacopœia contains many, many of the supplies upon which we moderns depend for the relief of pain and the prevention of disease. To be sure, their use of these things was in simple and crude forms, while modern laboratory practice has refined and made chemically pure and combined elements with exactness.

But there had to be a beginning somewhere, and the Indians who wandered over the hills and valleys of the American continent, were shrewd observers and very keen in their ability to draw interesting deductions. They noticed particularly the actions of ailing animals, and the traditions of the women of the tribe concerning healing potions were carefully preserved.

In those early days the different tribes or families of Indians prided themselves upon the number and knowledge of their medicine men and women, and these people were looked upon with great respect, even reverence, and had a surprising amount of influence over the members of the tribe.

The medicine men and women gave particular attention to disease, and according to Professor Heber W. Youngken, the usual procedure of these primitive professionals was much along the following lines:

"He (the Indian medicine man) first inquired into the symptoms, dreams, and acts of the patient, whom he examined, and then gave his opinion as to the nature of the ailment. This was generally mythical. He then prayed, advised, or sang to the accompaniment of a rattle, and made passes with his hand, occasionally moistened with saliva, over the part affected. Finally, he placed his mouth over the most painful spot and sucked hard to extract the immediate principle of the illness. This result he apparently accomplished, often by means of sleight of hand, producing the offending cause in the shape of a pebble, thorn, hair, splinter, or other object, which was then thrown away or destroyed. Finally he administered a medicine and often with it a protective fetish.

"The fetishes used included peculiar shaped stones, feathers, claws, lightning riven wood, hair, and pieces of pottery ornamented with mythical animals, representations of the sun, lightning, etc. These were believed to embody a mysterious power capable of preventing disease and counteracting its effects. There were numerous variations of this method according to the requirements of the case. If the case would not yield to simple treatment, a healing ceremony was sometimes resorted to. If all means failed, the medicine men suggested a witch or wizard as the cause. The designation of some known person as the culprit often placed his life in jeopardy. Often, when the medicine man lost several patients in succession, he was suspected by his tribe either of having been deprived of his supernatural power or of having become a sorcerer, the penalty for which was almost always death."

The deaths devised for the unsuccessful doctor were of a terrifying nature, as they felt that these leaders of theirs had deliberately betrayed them. Within the memory of the writer, such a death was dealt to a medicine man of the far East, by means of a barrel filled with spikes projecting into the interior of the barrel. The medicine man was put into this and the barrel rolled down steep hills until life was extinct.

It is evident from the treatment given by the medicine man that he himself was fully aware that part of the process at least was bluff. He knew that the confiding Indian who was injured or affected with disease expected some visible cause to be produced as an excuse for the pain or discomfort. And so to satisfy the patient, the sleight of hand was used to produce something which could be regarded as a contributing cause at least of the distress. The prayer and the use of magic really had their value in distracting the attention of the patient, and in arousing the elements of mental belief in the benefits to be derived. We now know that mind has a decided influence over matter, and the scenery arranged appealed to the Indian and his imagination.

After the stage was set, the medicine which was really to do the business was administered, and lastly the fetish or protective charm was given as a further visible means of keeping the Indian in line and stimulating his cooperation in the treatment.

From this it is obvious that, as Professor Youngken tells us, "Indian medicine of the past has been largely a mingling of charms and herbs."

We must not forget, however, that these people and even many of the old squaws, were thoroughly familiar with herbs and remedies to meet the ordinary ailments, such as colds, coughs, constipation, and other ailments. It was usually when the disease was beyond them that they appealed to the medicine man and expected him to make good. In some tribes of Indians the loss of four patients was sufficient to cause tribal vengeance to be heaped upon the medicine man.

It is stated on good authority that long before America was settled by the white man that the North American Indian was acquainted with different and effective "cough and cold remedies, emetics, cathartics, diaphoretics, vermifuges, astringents, alteratives, stimulants, narcotics, and antiseptics." Without doubt, they had little if any idea how these agents relieved and cured, but they were satisfied to know

that this drug or herb, or that mineral potion relieved the condition which caused the suffering.

Most of the Indian remedies of this early and crude materia medica were of the plant or vegetable kingdom. Roots, barks, leaves, stems, fruits, flowers, pollen, seeds, rhizomes, entire plants and combinations of different parts of different plants were used, both in the fresh or dry state. As a rule, most of the tribes used a single remedy in the medication offered, but some of the more advanced people combined two, three, four, or even five different ingredients.

The forms in which this medication was given are interesting. Sometimes the Indians chewed the barks and leaves, thus making a crude decoction; or again, they steeped and brewed, making teas and infusions. They prepared lotions, and ointments, and liniments for external applications, and plasters enjoyed a high reputation of efficacy among them.

Most of the remedies were of the decoction type, prepared by boiling, although the more subtle infusion made by steeping or soaking was also employed. They had dishes of earthenware and stone, and even beaten metals and dishes of wood and bark were used in the hot ashes with fair success. Liquids were heated either over the coals or over covered heat, or by dropping stones into them.

The Indian medicine man was well paid for his services. Sometimes he exacted his reward in advance, and sometimes he awaited results. The pay was of different kinds, "wampum, moccasins, the best bow, arrows, furs, venison or other food."

Both the medicine men and women were people of wealth and importance, and anyone who defrauded them of their compensation for their services was supposed to be visited by the wrath of unseen spirits. In fact, liberality was one of the ways in which the patient could cooperate for his own best good—or so it was supposed.

Sometimes if the patient was extremely ill, the whole tribe assembled and had a great jollification at his expense. This was supposed to propitiate the gods. Professor Youngken tells of the Mountain Chant practised by the shamans or medicine men of the Navajo tribe.

The people came together and spent nine days carrying out an elaborate program of dances, chants and incantations. The more expensive the feasts and program, the better it was supposed to be for the patient. It would seem as though the Indian needed to be stoical to a remarkable degree when he contemplated paying for such a powwow in addition to giving up his choicest treasures to the medicine man. Whether the Indians had a synonym for profiteers and grafters is not certain.

Our own forefathers, who were pioneers in the wilderness, did not have many available remedies at hand, and they in turn learned the value of many native herbs and drugs from their Indian neighbors. So that in reality we owe these people a debt of gratitude which we should not overlook.

Professor Youngken has compiled an interesting list of drugs actually used by the North American Indian, and doubtless there were many, many others known to the different tribes, and concerning which information has been lost.

The recent trip of Dr. Rusby into the interior of the South American continent has interested all familiar with the possibilities of his discoveries, for it has been recognized for some time that the primitive people of those regions know of native drugs which are strangers to us, and it is further possible and even probable that plants unknown even to the natives hold within their elements beneficent influences once they can be analyzed and tested.

The following is the listing given by Professor Youngken and is of a nature to cause most of us considerable astonishment.

VEGETABLE DRUGS

Balsam of fir.—Externally for cuts and sores; internally for colds in form of decoction of bark.

Milfoil.—As a compress or tea for swellings, earache, and stomach troubles.

Sweet flag.—Employed by all of the tribes as a carminative and by some for colds, fever, toothache, and other maladies.

Maidenhair fern.—In decoction for chills and fever and as a poultice for rheumatism.

Peyote.—This drug, representing the crown of a spineless cactus, is employed by the Plains and other tribes in a religious ceremony. From ten to forty disks are eaten by each participant. The first effect is excitement of the brain which is quickly followed by a derangement of the sight centres, causing a kaleidoscopic flow of colorful scenes of beauty. An excessive dose often causes unpleasant scenes.

Spikenard.—The rhizome and roots were used as a carminative and expectorant or with horseradish root as a poultice in dropsy. The juice of the berries and oil from the seeds were poured in the ears for deafness.

Jack-in-the-pulpit.—The powdered corn was employed externally for headache, rheumatism, and muscular pains.

Virginia snakeroot.—Chewed and spit upon wound for snake bite; bruised and placed in hollow tooth for toothache; the decoction used for fever and cough.

Canada snakeroot.—Used as a remedy for stomach disorders.

Pleurisy root.—Used internally for pulmonary troubles and applied externally in powdered form to wounds and old obstinate sores.

Flowering dogwood.—The bark was used for fever and colds.

Showy lady's slipper.—Used as a sedative in nervous disorders.

Smaller yellow lady's slipper.—A decoction of the rhizomes and roots in which was placed red fleshy stalks of a chickweed was used for worms in children.

Jimson weed.—Used as an intoxicant in initiatory ceremonies, as a narcotic and anesthetic, and in the treatment of wounds and sores.

Canada fleabane.—A decoction of this plant was used for diarrhea, while the ray florets were crushed between the fingers and inserted in the nostrils to cure rhinitis.

Button snakeroot.—Used as a remedy for snake bite and, in combination with blue flag, as a febrifuge and diuretic.

Wahoo.—The decoction of the inner bark was employed for uterine troubles.

Chronic Appendicitis

I. BOAS, M.D.

Berlin, Germany

If it is true that the woman that is the least talked about is the most virtuous, and if we apply this statement to the subject under discussion, then chronic appendicitis is undoubtedly the most maligned of internal diseases. In the work of decades, streams of ink and endless debates have been concerned not only with acute but also with chronic appendicitis. Even by bringing this question before you again I am not aiding in the improvement of the views and the evaluation of chronic appendicitis, especially since I do not offer you much that is new. It is only the fact that we internists and specialists see so many indefinite and doubtful, cured and uncured, cases of chronic appendicitis that has induced me to write on this subject. But there is still another factor: Today we discuss the question of appendicitis in a much more quiet and less heated atmosphere than we did decades ago, when the differences of opinion between surgeons and internists were pronounced and made an agreement difficult.

I shall confine my remarks on this subject accordingly to chronic appendicitis exclusively, and owing to the short space of time allotted to me I shall be compelled to limit myself to a few sidelights, and by omitting the extensive literature and numerous individual questions I will emphasize only the points that are of most importance to the clinician and the physician.

First, as to the question, is there, after all, such an entity as chronic appendicitis? With this question we enter into the midst of the discussion. The pathologists and numerous surgeons deny the occurrence of an originally, that is, primarily developed chronic appendicitis, and recently Aschoff, one of the best authorities on this subject (and also Jul. Schnitzler) has preceded his lecture in an excellent critical review on the present status of the question with the significant title On the Socalled Chronic Appendicitis.

This view is undoubtedly founded on a correct basis. In short, it may be admitted that every case of chronic appendicitis was at some time preceded by an acute forerunner. On the other hand, the experiences of Aschoff, Sonnenburg, Renvers, Kukula, and others, that a pathologicoanatomically and histologically changed appendix is found in advanced age in almost eighty per cent. of all persons, speak in favor of the fact that cases of originally chronic inflammations of the appendix with probably latent or uncharacteristic symptoms are observed clinically. This view is also in a certain agreement with our conventional clinical conceptions of chronic inflammations in other organs. We speak of a chronic gastritis, of a chronic enteritis and colitis, of a chronic pharyngitis, cholecystitis, etc., and admittedly associate with it the theory, that there is a chronic irritation that afflicts the mucous membrane of the particular organ, without denying thereby the possibility of a former acute forerunner. For me it is also beyond a doubt that there are slight painful conditions that pass off within a few days without fever and are limited to the regions of the cecum and the heart, which later on are labeled conventionally with the incorrect diagnosis of irritation of the appendix. Considered from a practical viewpoint, therefore, the question whether chronic appendicitis must be traced to a persistent irritation of the mucous membrane of the appendix, or whether the first insult was an acute forerunner, is, according to my conception, purely an academic one.

Things are different, however, in the primarily hyperacutely developing appendicitis and its consequent chronically developing recurrences. This, as I called it twenty years ago, residual appendicitis, has nothing in common with the course, nature, its whole clinical significance, and, finally, the treatment (I cannot here enter into greater details) of chronic appendicitis. It has its own peculiar appearance diagnostically, prognostically, clinically, and therapeutically.

I now wish to turn to the clinical picture of chronic appendicitis. Leaving aside all casuistic details and in a general review of that large army of truly or apparently sick patients with appendicitis, the statement that a truly characteristic disease picture of chronic appendicitis does not exist must be emphasized. What the patients complain of are always the pains in the region of the right ilium, which are aggravated by active movements and other bodily exertions and relieved by rest, which raise the suspicion of the presence of a slight inflammatory pro

cess in or in the region of the appendix, but a typical disease picture, a typical past history of disease or development of the disease, as it occurs in duodenal ulcer or in cholelithiasis, is not encountered in the disease under discussion. What is especially absent is the demonstration of definite disturbances of function, to which I will return later. How can we arrive at any definite conclusions when we know so little regarding the function of the appendix and when we actually consider it as a functionally unnecessary organ?

In 1905 I called attention to this subject with special emphasis upon the close relationship between chronic appendicitis and colitis in a lecture before the Verein für Innere Medizin. Today, since I have gained considerable experience, I can say that while there are cases in which the subjective symptoms are confined only to the appendix with complete integrity of the colon, they are extremely rare. Whether the inflammatory process is diffuse or is essentially confined to the cecum, whether it runs its course clinically as habitual obstipation with or without a simultaneous spastic attack, whether obstipation alternates with diarrheas, whether the cecum is dilated—whether there is the much discussed typhlatony or not, whether the cecum is movable (cecum mobile) or not—all these are subordinate points of discussion. The important feature, and, as I would like to say at this time, the confusing element in the clinical picture, as well as in the diagnosis and therapy, is the close relationship between the involvement of the cecum and that of the appendix. We internists repeatedly see this relationship in the appendectomy cases. At the same time, according to my observations, the assumption of Kümmel and others, that in cases of appendicotyphlitis, the appendicitis is the primary and the typhlitis, or more generally expressed, the disturbances in the colon, are the secondary factors does not hold. Cases, in which a chronic obstipation or a chronic colitis is cured by appendectomy, are at least among the great rarities. In surgery and in internal medicine the idea that the intestinal symptoms remaining after an appendectomy are attributable to adhesions has for a long time developed into a sort of dogma. I do not by any means deny their occurrence—Haberer has for a long time described a series of such cases—but on the basis of my own experiences acquired in numerous operations, I assert that the adhesions do not play such a controlling part among the sequelæ of appendectomy as is frequently taught and written. A large number of patients after an appendectomy suffer from disease of the cecum, and even before the removal of the appendix have either suffered from it alone or simultaneously with an inflammation of the latter.

Our entire knowledge of chronic appendicitis would probably stand on a firmer foundation, if in the future, as was the case formerly, we would again pay more attention to the cecum. For there is a lasting and lively functional association between the cecum and the appendix in the sense that the influx takes place more readily than the outflow. In the language of political economy the appendix is in a state of passive balance of trade. The inflow exceeds the outflow, and the latter is often almost nil. As a result of this there is the possibility of frictions, irritations, inflammatory processes, thickenings of the mucous membranes, obliterations, hydrops formations, empyemas, and other conditions. At the same time it must not be forgotten that, in contrast to the almost sterile ileum that it is in the cecum that the effects of bacteria first become evident, which naturally also infect the appendix and, as a result of the narrowness of the canal, find an excellent soil for propagation. It should also be borne in mind whether the still active peptic ferments are not mixed with the cecal contents, namely with rapid peristalsis, which may lead to all kinds of effects upon the mucosa of the appendix, which has no powers of resistance in the presence of numerous epithelial defects. I would like to call attention in this respect to the interesting studies of Heile (1) in which the great significance of the existence of noncatabolized food remains, together with the ferments of the small intestine in appendicitis is plainly shown. Although the work of Heile refers only to acute appendicitis, it undoubtedly applies also to the etiology of the chronic forms. However this may be, the close relationships between the cecum and the appendix are not to be denied, and there is also such a pronounced symbiosis in the pathology of these conditions, that a separation of these two, considered from both the biological and the clinical viewpoint, is a mistake.

This hand in hand relationship between typhlitic or colitic with appendiceal processes, results in it being impossible for the disease picture of chronic appendicitis to be sharply circumscribed and well demarcated. Only in the cases in which a simultaneous involvement of the cecum or of the distal portions of the colon can be clinically eliminated, does the thought of a chronic inflammatory process step into the foreground in the presence of lasting or frequently recurring painful conditions in the right ilium. The fact that there are still numerous disagreements among pathologists regarding the limits at which changes in the appendix should be considered as pathological, or still as physiological, contributes still more to our deficient knowledge of the nature of chronic appendicitis. I have already mentioned the fact that we also find changes in the appendix under physiological conditions, namely in elderly individuals.

The marked psychogenic insult, which some cases of true or doubtful chronic appendicitis reveal, is of significance in the clinical evaluation and, as I will show later on, in the diagnosis. The literature on chronic appendicitis is exceedingly rich in such experiences, and even though Liek of Danzig has attached the greatest importance to the spastic conditions of the colon in an extraordinarily valuable treatise on this subject, these are, nevertheless, only the partial symptoms of a general neurasthenia or, to express ourselves in a modern way, the sequelæ of an irritative effect on the autonomous nervous system.

It is therefore evident from the clinically and etiologically but slightly characteristic described disease picture that the diagnosis of chronic appendicitis also must stand upon a weak footing. The very fact that according to various surgical statistics mistaken diagnoses were made in no less than thirty-five to forty per cent. of the cases of appendectomy at operations for chronic appendicitis, indicates that diagnostically we do not as yet stand on firm ground.

Before entering upon this subject more deeply I would like to preface my remarks with the statement that the diagnosis of chronic appendicitis is by no means a snap diagnosis. This is an important point, inasmuch as the opinion prevails among many physicians and also in the public at large, that the question whether a chronic appendicitis exists or not can be decided without difficulty by the single palpation of the appendix region. We can arrive at an absolutely definite diagnosis only by the process of exclusion. This means that we must limit the diagnostic possibilities in such a way by the exclusion of disease pictures presenting other similar symptoms, that only the assumption of an appendicitis remains as the most probable expression of these symptoms. It needs hardly be mentioned that such an excluding diagnosis requires numerous examinations and observations, and frequently also the aid of other specialties.

Of the diagnostic aids that require consideration, the following four ought to be discussed:

In the first place let us consider the much discussed points of tenderness. Of these, as is well known, the McBurney point enjoys a special significance—one can almost say a universal significance.

Furthermore, during the course of years quite a large number of other points of tenderness have also been discovered and recommended for trial: they are attached to such names as Munro, Lantz, Clado, Lentzmann, Morris, and Kümmel. From the critical point of view all these points of tenderness differ little from one another, one often being only a centimetre's breadth to the right or left, or somewhat at a higher or lower level than the other. Hausmann says the following of McBurney's point—and the same applies also to the other points: "A geometrically determined point on the abdominal wall can never correspond to an inconstant point in the abdominal cavity, such as the point of insertion of the appendix." Furthermore, if we consider how many changes of position the cecum, and with it the appendix, shows, it is plainly evident what great mistakes must be associated with conclusions drawn from this or that point of tenderness.

A distinct advance in regard to the better localization of the tender appendix is undoubtedly the procedure of Singer and Holzknecht (2), who determine the seat of the tender area röntgenologically with the aid of the Holzknecht spoon indicator and have thereby taught us to differentiate the regions adjacent to the cecum from other parts. According to my knowledge additional proof of this technic has not been brought forth. It may undoubtedly aid in lending a certain support to the diagnosis, on the one hand, and to disprove it and to direct the attention in another direction, on the other.

Hyperalgesia of the skin is a factor that makes the determination of tenderness extremely difficult, as this may occur not only alone, but also in association with an involvement of the appendix. In every hyperalgesia of the skin, which, as I emphatically remark, may, as such, lead to appendicitis like symptoms, one should seek for corresponding hyperalgesic zones in other regions of the abdomen. The diagnosis of pseudoappendicitis or psychogenic appendicitis is considerably facilitated by the finding of numerous hyperalgesic areas in the skin. I would also like to call attention to a method, which has rendered me good services in the differentiation of a mere hyperalgesia of the skin from a simultaneously occurring deep seated tenderness—that is, the treatment of the hyperesthetic zones for several days with Bier suction cups. I have found that if the sensitive area is made hyperemic twice daily for three to four days for periods of half an hour each, the hyperalgesia of the skin disappears, whereas the deeply located tenderness remains. With this simple procedure I have been able to eliminate a large number of cases of pseudoappendicitis; on the other hand, after the elimination of the cutaneous pains one can readily tell whether an inflammatory process is going on in the depths of the appendix region or not.

According to my experiences, a circumscribed point of tenderness in the vicinity of the attachment of the appendix is of special significance in cases of socalled appendicular colic. I believe that I can safely say that this form of colic occurs more frequently than is generally believed, but that in spite of its peculiar course it is seldom recognized. I can therefore briefly discuss the disease picture of appendicular colics, to which Talamon was the first to draw attention. It is characterized by suddenly appearing, severe attacks of pain, attacking the entire abdomen diffusely, which disappear after a few hours, but leave after their cessation a distinct subjective (which is the most important) and also an objective tenderness in the vicinity of the appendix, which remains for several days and then recedes. Similar attacks, with exactly the same palpatory findings, may recur in the course of weeks or months. I know, of course, that stones in the ureter and the kidney may produce the same or a similar symptomatic picture under certain circumstances, and I also admit that acute or recurring diseases of the adnexæ may produce a similar disease picture in females. But, by exclusion of the same, it is my firm belief, it is justifiable to establish the diagnosis of appendicular colics and to draw therefrom the necessary conclusions.

Accordingly, if we are to expect anything from the application of a point of tenderness and are to draw any conclusions from it, a number of important prerequisites must be seriously considered. The omission of the same is probably the reason why, as I believe, these points of tenderness have been so notoriously disregarded in recent times by the majority of surgeons. The first prerequisite is that the point of tenderness should be found constantly in the same spot; the second is that it should not be a skin or muscle pain, and the third is that, with the exception of this point of tenderness, no other possible tenderness should be demonstrable in that region. The moment that the tenderness is not strictly confined to the region of the appendix, but extends to parts of the colon or cecum, it naturally loses all value and every diagnostic significance. Naturally, under these conditions the appendix may also be involved in addition to the cecum, but we can then give no diagnostic opinion regarding it, at least on the basis of the palpation.

Another question is, whether the absence of a point of tenderness at or near the attachment of the appendix excludes the existence of a chronic appendicitis. The answer is no. I have already shown above, that in appendicular colics the tenderness is closely associated with the attacks, again to disappear after

a few days, and the same statement applies to the slight, periodically recurring attacks of pain in the appendix. In the painless stage and in the presence of absolute painlessness of the appendix, we can express an opinion, as to whether it is diseased or not, only with extreme caution.

I must emphatically contradict the statement found in the literature and based upon the examinations of young students by Keith and Treves, that a tenderness over McBurney's point or similar points are demonstrable in the vast majority of healthy persons. This can be admitted only, as I certainly have been able to observe not rarely, when the appendix region is brusquely manipulated with the hands. A carefully practised palpation of the cecum or its surroundings is entirely painless, as I most certainly assert in healthy individuals.

Summarizing, I would say regarding the diagnostic significance of the points of tenderness, that they have no decisive value, but that together with the entire symptomatic picture, namely with a constantly persistent location in a closely circumscribed area and with the elimination of merely cutaneous tenderness, they probably indicate a diseased condition of the appendix. Although the absence of a point of tenderness does not exclude a chronic inflammation of the appendix, it, nevertheless, alone does not allow any opinion in the positive or negative sense.

I can be brief regarding the second diagnostic method—the palpation of the appendix. Even though such an experienced palpator as Th. Hausmann says that the appendix can be palpated at the most in fifteen per cent. of the cases, and this only under certain definite conditions, and if one considers also that not every palpable appendix is always chronically inflamed, it is easy to see the slight significance of palpation of the appendix. According to my personal experience the palpation of the appendix is a purely accidental finding and we cannot speak of its diagnostic value in a general sense.

Slight rises of temperature may also have a certain significance in diagnosis, and this in two directions. There may either be transient rises of temperature in acute exacerbations of chronic inflammatory conditions, or there may be persistent slight rises of temperature. Attention has been called both by myself and others to the disparity between the axillary and rectal temperatures. The above mentioned rapidly passing rises of temperature are the most valuable. Unfortunately it is only rarely that we are in a position to determine it with certainty and to evaluate it accordingly. With persistent rises of temperature we must, as I agree with W. Neumann and Schnitzler, be very reserved in our decision, as there may also be other causes of fever, such as latent tuberculosis not only of the lungs, but also of other organs, genital affections, insidiously coursing processes in the kidneys, the biliary passages, and other conditions. We are still left considerably in the dark and remain so, regarding various other causes of slight rises of temperature, as I have been able to convince myself through years of experience.

Röntgenographic demonstration of the appendix, which has been undertaken by many authors in recent years, especially in regard to the lesser or greater capacity of the appendix to empty itself of the contrast medium, plays an important part in diagnostic evaluation. As a matter of fact we initiate with it for the first time the conception of a truly functional method. It takes its origin in a direct proof of motility in a röntgenological manner, which has also proved itself extraordinarily valuable in the diagnosis of gastrointestinal diseases. The questions that arise in this respect are of various sorts: 1. How often does the appendix fill itself under normal conditions and how often in pathologically changed appendices? 2. How long does the appendix remain filled in pathological, in contrast to normal, conditions? 3. How does the normal and the diseased appendix behave, not only toward firm, but also toward fluid contrast media? As far as I know, this question has not yet been investigated, but it appears to me that we ought to be able to gain information in this manner regarding the extent of some stenoses and obliterations.

Recently a number of interesting preliminary articles by Almens, Rappaport, L. Kuttner, and Czepa have become available for the functional test of the appendix. The observations of Kuttner in conjunction with Arth. Fränkel, that in disease of the appendix residua of the contrast medium are encountered after several days, even though the colon has been entirely freed of the contrast medium with a purgative, appear to me to be of considerable diagnostic significance. With this method Kuttner, for example, was able to make the correct diagnosis of chronic appendicitis in many cases, in which there had been a suspicion of gastric or duodenal ulcer and, accordingly, to have these patients successfully operated upon.

In my private clinic I have myself frequently used the method of Kuttner and Arth. Fränkel. The number of examinations, however, is not yet large enough to allow me to make a report. Nevertheless I believe that the functional test of the motility of the appendix is valuable in the diagnosis of chronic appendicitis, which may well surpass all the others in significance on further confirmation.

In addition to the symptoms mentioned, there is still another group, which I will mention only briefly, because they appear to me to be extremely uncertain, for example, distention of the rectum with air proposed by Dreyer, the air cushion symptom emphasized by Klemm, the Rovsing sign of counter pain, muscle tension, and others. The reference to the diagnostic significance of the rectal examination is also frequently found in the literature. Just as highly as I value it in acute appendicitis, just so insignificant has it been, according to my experiences, in chronic appendicitis.

Owing to lack of space I can only touch upon the differential diagnosis of chronic appendicitis only in a few words. Fundamentally, one or more differential diagnostic considerations are associated with every diagnosis of chronic appendicitis. The important ones are almost always the typhlitis or colitis, ureteral or renal calculi, and the genital apparatus in females. In colonic spasm and other neurasthenic symptoms, the possibility of a psychogenic involvement of the appendix must be taken into account. In addition, even though much rarer, atypical forms of cholelithiasis and, as mentioned, the parapyloric ulcer may come up for consideration. And so there will also be other cases of appendicitis, which, in the

sense of Ewald, are and, unfortunately, will also remain latent.

Essentially it will be a matter of thinking of all the various possibilities and, accordingly, of utilizing all the necessary clinical methods of examination, the details of which I naturally cannot discuss. I wish only to call attention to the fact, there being no reference to it in the literature, that latent or slightly developed inguinal hernias may simulate the picture of chronic appendicitis. I know of a large number of cases, which had passed through many hands unsuccessfully, and in which I have permanently relieved these forms of pseudoappendicitis of their symptoms, simply by a truss.

Finally, the question must also be answered, whether in the present state of our knowledge we are able to recognize other diseases of the appendix and its surroundings, such as the rare carcinoma, tuberculosis, actinomycosis, invagination, diverticulum of the appendix, and others, and to differentiate these from chronic appendicitis. I must say no. All of these conditions can be determined only by biopsy or necropsy. According to our present diagnostic aids we can do no more than make a diagnosis of chronic appendicitis.

I now turn to the therapy of chronic appendicitis and I will first raise the question: Is there an effective internal treatment of the same? In so far as the processes of the appendix associated with true, organic changes are concerned, this question—about this there is no doubt among men of experience—must be answered in the negative. One may indeed bring the symptoms of the chronic inflammation temporarily into a state of latency by means of extensive rest cures, cataplasms, hyperemia treatment, by a rational diet and regulation of the intestinal activity, but we cannot speak of a really permanent cure in the true sense of the word. Occasionally spontaneous cures may possibly occur in the very slight initial forms of appendicitis, the socalled irritations of the appendix, or in appendicular colic, and these may be favored by the measures mentioned above. Permanent cures may also be achieved in pseudoappendicitis and in the psychogenic forms of appendicitis, partly by mere suggestive treatment and partly by instrumental or pharmacological psychotherapy. On the whole, however, we can hardly speak of permanent cures in the true chronic inflammatory conditions.

What attitude should the internist take toward the surgical treatment of chronic appendicitis? We cannot dismiss this question with the very popular and easy statement of the individual point of view. We must at least attempt to establish certain rules.

The difficulties lie mainly in the absence of definite diagnostic evidence, which I have already sufficiently illustrated heretofore. Critically speaking, the surgical intervention is an exploratory laparotomy in the majority of cases. But even more than that, many surgical interventions are nothing more than an exploratory therapy. Finally, the therapy is not convincing under all circumstances. Several years ago Krecke of Munich reported upon twenty cases with appendix symptoms, in which the appendix was extirpated. The most careful search in these cases showed neither macroscopic nor microscopic evidence of an inflammatory process. Nevertheless, a subsequent questioning of seventeen of the patients operated upon (eighty-five per cent.) revealed some enthusiastic reports upon the excellent curative results. These were undoubtedly appendicitis cures produced psychogenically.

All of these circumstances make it difficult for the physician with a sense of responsibility to draw any conclusions. After all the diagnostic aids and the differential diagnosis are exhausted, he must truthfully admit to the patient that according to the present state of our knowledge more than a probable diagnosis cannot be made, and that a definite promise of a cure cannot be given, but on the other hand, that the prognosis for a cure is certainly favorable with a relatively harmless intervention. On the other hand, appendectomies must be distinctly warned against in psychogenic appendicitis. The fact that in recent years attention has been called emphatically by recognized surgeons, by Küttner and his pupils Melchior and Löser, by Liek, Schnitzler, and others, to the serious sequelæ that are associated with appendectomies in cases of pseudoappendicitis, is greeted with great joy.

That much for the general indications. In special conditions I am in favor of operative intervention in the following conditions: In the first place, in children, in whom continued rest cures and protective measures constitute an extremely difficult factor in physical and mental development. In the second place, in adults in whom the differential diagnosis between appendicotyphlitis, or appendicocolitis and appendicitis is impossible. This diagnostic uncertainty also has its effect upon the therapeutic uncertainty. Typhlitis with its various modifications demands entirely different therapeutic measures than chronic appendicitis, and often just the opposite. In one word, we are not masters of the situation. Only after the appendix is removed, do we again stand on firm soil therapeutically. Undoubtedly, with this attitude, we will now and then be compelled to unnecessarily remove an appendix. In this dilemma, from which we as physicians cannot escape, and which affects the nervous system of the patient at least unpleasantly, it appears to me to be better to sacrifice a normal appendix, than to be constantly shifting about diagnostically and therapeutically. The end will be appendectomy whether we wish it or not.

I also consider appendectomy as indicated in the constantly recurring appendicular colics, provided they can be assumed to be probable or certain on the basis of the points mentioned heretofore.

Finally, in agreement with Schnitzler, I am in favor of appendectomy in cases where severe acute cases of appendicitis have occurred frequently in families and a member of such a family is suffering at the time from recurrent painful conditions in the cecum or in the appendix. Even if the diagnosis may be doubtful—of course, not in typhlophobia—I am in favor of operation, particularly in children and in young adults.

There are undoubtedly other indications for the removal of the appendix, but those mentioned will be encountered most often.

As you may see from my conclusions, chronic appendicitis is a pleasant disease for neither the surgeon nor for the internist, because we can master it neither diagnostically nor therapeutically. But just as in

other specialties, I hope that in this also an intelligent cooperation of surgery and internal medicine will endeavor to straighten out differences and to clarify confusion.

Chronic Appendicitis from the Surgeon's Viewpoint

H. HABERER, M.D.
Graz, Austria

It is a difficult and thankless undertaking to speak of a disease picture from the viewpoint of any clinical branch of knowledge when the right of its existence is questioned by the pathologist. A number of clinicians, among whom Sprengel is the foremost, endeavor to adduce evidence that there is a form of appendicitis which runs a chronic course from the beginning. In the field of internal medicine, it was predominantly Ewald, who under the terms of appendicitis larvata reported upon a disease picture, which, aside from the typical cases of appendicitis, gives rise to more general abdominal symptoms, so that these cases can be correctly recognized as appendicitis by the physician often only by the the process of exclusion and by the positive symptom of tenderness at the typical site. This form of appendicitis with a purely chronic course is now generally looked upon by the pathologist skeptically, and Aschoff, as a result of his findings, maintains that there is no such a condition as a primary chronic inflammation of the appendix, but that everything that suggests chronic inflammatory changes in this organ is nothing else than the residuum of a past acute inflammation. With this negation of the pathological anatomy the clinical aspect of chronic appendicitis as a disease sui generis falls away, if we wish to cling to a strictly scientific basis. Nevertheless, chronic appendicitis as a primary disease of the appendix is still defended today by clinicians of great experience, among which I will mention two names—Kümmell, who has always defended it in his speeches and writings, and Lanz, who even looks upon an acute attack of appendicitis as the flaring up of an old preexisting chronic appendicitis. I myself must admit the guilt of having reported cases in 1907 under the terms chronic adhesive appendicitis, which might even give the impression of malignant tumors. As a matter of fact there is in these cases a basic appendicitis, which runs its course without attacks, but which often produces severe symptoms as a result of chronic inflammatory changes in the ileocecal region. I will return to a consideration of these cases shortly. First of all, however, attention must be called to the fact that a surgeon like Schnitzler, who has had special experience in this very question, takes a more than skeptical stand against the justification for the existence of a purely chronic appendicitis.

If we adhere strictly to the pathologicoanatomical viewpoint, and we cannot swerve from this clinical manner of thought which has become a law, then we must support the view of such an experienced pathologist as Aschoff, namely, that every chronic appendicitis is the natural result of an acute inflammation, a course which we are very frequently accustomed to see in what we call inflammation. We must certainly admit that it is much more like the nature of the pathologicoanatomical processes that we know, when we see a chronic inflammation gradually follow an acute inflammation, than the reverse, when an inflammation running a purely chronic course from the beginning shows a flareup in the form of an extremely acute inflammatory process. At any rate, as I have already mentioned, the latter possibility is nevertheless assumed to exist by some clinicians and an attempt is made to support it by such observations.

In regard to the practical medical working out of this originally pathologicoanatomical question, it must be conceded that it would be of subordinate significance for the medical diagnosis of the individual case if it were possible to diagnose a chronic appendicitis with certainty from its symptoms. It is just this difficulty in making a diagnosis that has frequently given rise to mistakes, which, because they were unrecognized again gave rise in part to an indiscriminate symptomatology of chronic appendicitis, which has flourished to such an extent that the statement may be made unhesitatingly that there are some physicians who, when they cannot find any anatomical tangible data, with even the most vague abdominal symptoms, seek the cause of the symptoms in a chronically inflamed appendix. That harm can be done in this way and has even been perpetrated is shown by those cases, which are not improved by an appendectomy based on such a poor diagnosis, or which are further complicated by additional symptoms attributable to new and resulting adhesions.

The patients whom we see with numerous laparotomy scars and persistent symptoms and make the statement that the first operation improved their condition with the removal of the appendix, frequently also lend support to the claims for an appendectomy that offers little hope of success.

Even if, as is selfunderstood, we have no right to criticize the method of treatment of a colleague without definitely knowing why he resorted to a certain procedure and what he found, it cannot, nevertheless, be denied that every experienced surgeon not very infrequently also sees another category of cases following appendectomy which are rather afflicted with an undoubtedly organic disease in the abdomen (according to my personal experience usually diseases of the gallbladder, duodenal or gastric ulcers, and diseases of the female genital organs) the carefully taken histories of which make it appear very likely that the condition had existed at the time of the appendectomy. How often these very patients claim that really nothing or only a very slight affection of the appendix was found!

Again, other patients do not go to the surgeon after the removal of a socalled chronically inflamed appendix but to the internist, and then soon augment the population of the sanatoria for tuberculosis.

All of these groups that are justly disappointed with the appendectomy show evidence that chronic appendicitis is diagnosed too often, and this is at least partly due to the difficulty of the diagnosis. I cannot agree with those colleagues who find even the diagnosis of acute appendicitis not easy and who base their belief essentially on the unreliability and inapplicability of the points of tenderness mentioned therein, but I do subscribe to the enormous difficulty which might arise when we must diagnose a chronic appendicitis without the finding of previous acute attacks in the history.

With these remarks I return to the evidence collected by Aschoff. Even though the pathologist can show us the residua of a past acute process in the chronically inflamed appendix, it does not prove that these acute inflammatory processes have produced any clinical symptoms, and still less that they were observed by the physician and properly interpreted. We know from hundreds of experiences that patients come into dispensaries with very severe empyemas of the appendix and even occasionally with already existing perforation, and there patiently wait, because they have no or almost no symptoms. How often does an acute attack of appendicitis run such a rapid course that the physician is called too late and a diagnosis is rarely possible!

I shall never forget two such cases because two persons very dear to me were affected:

The first case was that of a very dear friend and colleague, with whom I was in almost daily contact during my Innsbruck activities, and who never had had even the slightest abdominal symptoms. During the best of health he watched me during an operation and then broke down about ten minutes later with the symptoms of an acute perforation. An immediate operation confirmed the diagnosis of an appendiceal perforation with an empyema of the appendix, which the colleague naturally, as he assures me even today, carried about absolutely without symptoms. This is a classical example of the cases familiar to us all of the existence of severe inflammatory changes in the appendix, which produce no symptoms so long as the peritoneum is not involved as well.

The second case was that of my own daughter, who suffered with very severe colics of extremely short duration from her second to her thirteenth year of life, which according to the description could hardly be of other than appendicular origin, but which I could only judge from hearsay, as I invariably had occasion to examine her only after such an attack, when there were absolutely no symptoms. I, myself, witnessed such an attack only in her thirteenth year of life, and this left no doubt as to the diagnosis and the immediately executed operation revealed, in addition to a fresh empyema of the appendix with fibrinous deposits upon the serosa of the same, a series of scars in the organ itself, so that it was plainly evident that the former attacks were actually referable to the appendix. This case is the best illustration of the occasional flightiness of slight attacks of appendicitis, when they can elude a father who is a surgeon, so that for eleven years he is not in a position actually to observe one of these attacks, and therefore could not make a diagnosis during all that time.

That many such and similar cases as the latter run their course under the conception of a socalled latent or chronic appendicitis, and others under the term of chronic adhesive appendicitis without attacks, is highly probable, and the attending physician in such cases must not be accused of illogical thinking, if there is an indefinite history, when he can gain the impression of a purely chronic course of appendicitis. In such a case it is the same as in many other fields of human pathology, that it is easier for the pathologist, who can examine the diseased organ under the microscope most minutely, than the physician, who must picture to himself the nature of the organic disease by an indirect examination and is also frequently dependent upon the statements of the patient, which are not so rarely unreliable, both as regards their sensation during the examination and their past history. It can thus happen that a laparotomy can even be done under a false diagnosis, when rather accidentally severe chronic changes may be found in the appendix with adhesions, as a result of which, for example, I at one time was inclined to include certain cases under the collective term of adhesive appendicitis without acute attacks. These very findings, however, as I was able to show at that time and since then have repeatedly observed, show that several inflammations had attacked the appendix, and that the term "without acute attacks" can therefore be justified only in a clinical sense, that is, saying nothing else than that the previous acute inflammatory symptoms were not sufficiently appreciable by either the patient or his attending physician. But no one, not even the greatest skeptic, will deny that such cases as I have just mentioned can be considered as chronic appendicitis in the stage in which they were operated upon.

If one takes into consideration also the relative frequency of appendicitis in childhood, with its frequently exceedingly great difficulty of interpreting the symptoms, in which every successfully overcome attack may leave behind residua in the appendix, and in which finally many years may pass but less severe symptoms eventually lead to an appendectomy, then one can easily understand why a belief in a primary chronic appendicitis has persisted so long in the mind of physicians. Moreover, those cases of chronic appendicitis, which are recognized as indurative appendicitis, and which, for example, may result from the destroyed appendix previously becoming agglutinated to its surroundings through a destructive inflammation and perforating through the peritoneum which lies over it as a protective covering, even though this is rarely the case, may run their course without symptoms up to the appearance of a hard tumor.

This also explains why these very patients occasionally are operated upon under a false diagnosis of tuberculosis or even of carcinoma. I certainly know of a number of such cases that were explained only by the findings at the laparotomy. Finally, we must also briefly discuss those cases, in which the chronic inflammation of the appendix is nothing else than the involvement of this organ in a chronic inflammation of the entire colon or selected portions of the same. In regard to these very cases the question has been raised whether a colitis is followed by an appendicitis,

or vice versa. I believe that this question has no basic justification. This question has been discussed illogically according to the law of *post hoc, ergo propter hoc.* It would be just as difficult to understand why the appendix should not be involved in disease of the entire colon, nor can it be understood *a priori* why disease of the small appendix should lead to severe changes of the mucous membrane of the colon, which under all circumstances is favored by more suitable physiological conditions. Even though cases in which the colitis was recovered from after the appendectomy are repeatedly reported, nevertheless these cases should be judged with the greatest skepticism, and may frequently be explained in this way, that the appendectomy first gave rise to a truly effective treatment of the colitis, or that the rest and diet necessarily associated with the operation improved or made the symptoms of the colitis disappear.

The variability of the anatomical findings in the appendix observed in chronic appendicitis (naturally only those cases are included in which the appendix shows any findings at all that might justify the diagnosis of inflammatory processes) makes it clear that the symptomatology of chronic appendicitis may also be extremely variable. All that has been written about the symptoms for which a chronic inflammation of the appendix has been made responsible cannot stand severe criticism, and also is undoubtedly responsible, as I have said before, for the fact that chronic appendicitis is diagnosed much too often. Generally speaking, there is hardly a single symptom that points to disturbances of the abdomen that is not also supposed to have been observed in chronic appendicitis. If one compares the slight symptoms with these frequently quite severe symptoms, and also the occasionally even absent anatomical changes in the appendix, the unreliability of this sort of a diagnosis is selfevident. I only mention that every sort of painful sensation in the abdomen, up to severe colics, digestive disturbances of all sorts, nausea and vomiting for which no tangible cause can be found, obstipation, on the one hand, and diarrheas on the other, and many others, have been mentioned as a part of the disease picture of chronic appendicitis. It is just these most contradictory symptoms, such as obstipation and diarrhea, hyperchlorhydria and hypoacidity that are included in the symptomatology of chronic appendicitis, to the diagnosis of which in general tenderness in the region of the appendix and slight, usually evening rises of temperature, are necessary.

Like König, I would like to make a few remarks on the most valuable symptom—the tenderness in the ileocecal region—when this is found repeatedly during various examinations, and I am not such a profound skeptic as Schnitzler in the evaluation of the points of tenderness. Even though we must agree with Schnitzler, that the large number of points of tenderness generally mentioned as valuable in appendicitis shows that the reliability of any one of them must be considered as problematical, in my opinion it may be said in reply, that, as a matter of fact, all these points of tenderness are not and cannot be points that correspond to the position of the appendix, which is a variable one, but of tenderness in the immediate vicinity of the diseased part of the abdominal cavity, which is usually associated with marked muscular spasm, and which I have for a long time designated as tenderness in the ileocecal region. It must certainly be admitted that this tenderness usually is a good guide in the diagnosis and cannot be set aside as too trivial, because it, at least in my experience, does not leave us in the lurch in the frequently not very easy differential diagnosis between acute appendicitis and a beginning central pneumonia, which, as is well known, might lead to subjective pains in the ileocecal region. I believe, even though I myself have had no extensive experience with this method, that one ought also to give consideration to hyperesthesia of the skin in the sense of Mackenzie and, at any rate, not to neglect this very simple diagnostic method. On the other hand, I fully agree with Schnitzler when he is opposed to the value of rises in temperature in the diagnosis of a chronic appendicitis, and I share his conviction that rises of temperature should be evaluated rather against than in favor of a chronic appendicitis.

Ever since I have been a clinical teacher I lay the greatest emphasis in my teaching upon showing the students the slight value of the behavior of the temperature in the diagnosis of acute appendicitis, because, according to my experience, the greatest number of unfortunate cases (in the sense that cases of severe acute appendicitis are referred for operation too late) are due to the fact that the attending physician does not make the diagnosis even though it is evident, because there is no, or in his opinion not a sufficient rise of temperature. I always emphasize the fact that a severe empyema of the appendix and even a perforation may occur without fever, whereas, for example, an oxyuris appendicitis in a child occasionally gives a temperature up to 40° C., although hardly any noteworthy changes in such an appendix are demonstrable externally.

And what applies to acute inflammation with all its pathological products, should this not also apply to the exquisitely chronic inflammation? It is just the cases with rises of temperature, which must give us the opportunity of avoiding a diagnosis of chronic appendicitis before any organic disease, especially one of the lungs, is excluded by every possible means.

As in every other condition, röntgenography has in recent times also been given much attention in chronic appendicitis. Even during the latter years of my activity at Innsbruck, the director of the Central Röntgenologic Institute there, Staunig, made some successful endeavors in the röntgenologic demonstration of the appendix, and in a similar way it was possible for Loeb, the director of the Central Röntgenologic Institute in Graz, to demonstrate the appendix with the fluoroscope. Certain changes in the position and form of the appendix, provided tenderness is demonstrable simultaneously by fluoroscopy, delayed expulsion of the contrast medium and residual spots, are significant in the frequently very difficult diagnosis of a chronic appendicitis. I must particularly agree with Kuttner, that the finding of residual filling in the appendix at a time when the rest of the colon has already completely expelled the contract medium, should be considered as a pathological röntgenological finding. The very aid that röntgenography has given heretofore in this respect prompts me in a few words to call attention to the significance of the position of the appendix and the nature of its

insertion into the cecum for the possible origin of a chronic appendicitis.

It was principally Hochenegg who called attention to these matters, which, naturally, were also subjected to criticism. In contrast to others, I maintain that abnormal positions of the appendix and, especially, the abnormal insertion of the cecum may very well give rise to abnormal filling conditions of the appendix and consequently also to abnormal conditions of irritation, as a result of which a chronic inflammation may develop in the course of time. But, naturally, a prerequisite is that chronic inflammatory changes be actually demonstrable in the appendix in each individual case. We must not, under any circumstances naturally, go so far as to defend obstinately the diagnosis of a chronic appendicitis, when this organ shows no changes worthy of mention. And this occurs, unfortunately, often, and, as a result, the existing confusion is made still worse.

At any rate, this question was brought up especially by the fact that all of the processes that develop in the ileocecal region that are associated with tenderness in this region, whether it occurs spontaneously or only during a physical examination, are identified occasionally with chronic appendicitis. In this respect we can refer to the classical description of de Quervain in the latest edition of his well known *Diagnosis*. Both the membranous enteritis, which remains confined to the cecal portion of the colon and the stercoral and ulcerative typhlitis of this portion of the gut are frequently and without thinking identified with chronic appendicitis as is cecum mobile, typhlectasia and typhlatony. We encounter here the same condition, as I have indicated heretofore, namely, that disease pictures with the very opposite result are identified with chronic appendicitis, and that such a procedure can and must have serious results upon the therapy hardly needs any further discussion.

It is a very well known fact, unfortunately, that in these proverbial cases, in which an appendectomy with cecopex had been done, it was followed by cecolysis, naturally done by another surgeon. Equally well done are the cases described previously, in which an unnecessary appendectomy is followed later by a laparotomy for an actual organic disease, which had already existed at the time of the appendectomy, but was not recognized. Finally, there also belong to this group the cases already briefly described, in which the appendectomy is the first step to multiple laparotomies, of which every one, especially the first, had better been omitted. Generally, these most unfortunate victims of this abdominal polypragmasia are recruited mostly from that group of individuals who, at any time and for various reasons, imagine themselves to be suffering from an appendicitis. Unfortunately, after a more or less diligent search, they eventually find a willing surgeon who removes the appendix. Other surgeons, just like myself, no doubt also find cases, in which, according to the dictates of conscience, an operation is advised against, but which do not rest until the operation is performed by some one and then ruefully return to the surgeon who refused to do the operation because of their usually more severe pains.

If one sifts out this artificially produced chaos, which is presented to you in bold outlines, little is left of what we may with a clear conscience call chronic appendicitis:

1. The cases, which it would not really be necessary to mention, in which following one or several acute attacks of appendicitis there develops a chronic change in the appendix, which continually produces symptoms. If acute attacks are observed by the physician, the diagnosis of secondary chronic appendicitis is naturally much easier and can be made with greater certainty even in the presence of less pronounced symptoms than when there is only the mention of acute attacks in the past history.

2. The cases, in which a chronic appendicitis actually exists without any demonstrable acute attacks having preceded it. This group includes, among others, the cases designated by Ewald as appendicitis larvata, the cases of chronic adhesive appendicitis, and some rare cases of socalled indurative appendicitis. The pathologicoanatomical findings in chronic appendicitis may be of various types.

The diagnosis of these cases included under group 2 may, under certain conditions, be exceedingly difficult; it will often be no more than a probable diagnosis and it will also include cases in which the diagnosis is impossible. The reason for this is, on the one hand, the exceedingly variable symptoms of which the patients complain, and the slight objective positive clues that are available to the physician, on the other hand. At this opportunity, I would again like to say that I, in contrast to the opinion of others, attach the greatest importance to the exclusive tenderness in this region, and also to the röntgenologic findings in the hands of an expert röntgenologist. This röntgenographic examination is to include the thoracic organs, and I would like to say that the diagnosis of chronic appendicitis in this group of cases is to be made only when the involvement of other organs or symptoms can be excluded with the same certainty as with which we can exclude such diseases. The fact that these are cases that run an exquisitely chronic course justifies a careful and a systematic röntgenographic examination.

3. Some cases of typhlitis cannot be differentiated from chronic appendicitis with the aid of the existing diagnostic means, this being especially so in this condition, as the appendix may also be actually affected. The disease pictures designated under the names of cecum mobile, typhlectasia, and typhlatony, in themselves, have no connection with chronic appendicitis, and, if we can at all speak of diseases, we must speak of them separately in order to avoid confusion. Whether surgical treatment is indicated in this condition, is a separate question, which in this connection, I would like to say, I am glad not to be compelled to discuss.

In regard to treatment, appendectomy is naturally indicated in the cases of group 1. Of the cases included under group 2, the indurative appendices occasionally require a special procedure in the sense that a partial intestinal exclusion through a lateral ileocolostomy should be added to the appendectomy, if the indurative adhesions, as is not too rarely the case, have drawn into themselves also portions of the lower ileum or quite large portions of the cecal wall. Otherwise, appendectomy alone is indicated in the cases cited under group 2. Whether this offers any hope of success in those cases of group 3, in which the

chronic appendicitis is only a partial phenomenon of a typhlitis, cannot be said in advance in the individual case.

If in cases, in which the diagnosis cannot be made with certainty, an appendix is removed—the slight changes of which cannot explain the abdominal symptoms of the patient—then this appendectomy, provided that any other organic disease was excluded with the greatest carefulness, can do no harm to the patient.

Appendicitis in the Hernial Sac

LEIGH F. WATSON, M.D.
Chicago

Appendical hernia is not common, being about as frequent as bladder hernia. Both of these varieties are most often found in subjects past middle life, and the appendix is usually accompanied by the cecum, omentum, or small intestine. On the other hand, isolated hernia of the appendix is found most frequently in infants under two years of age.

The appendix was first distinguished by Berengerius Carpus in 1524, described by Vesalius in 1543, and by Fallopius in 1560. In 1561 Vidus Vidius gave it the name of appendix vermiformis.

De Garengeot, in 1731, was the first to describe the appendix as a content of a hernial sac. The next case was reported by Amyand in 1736, and another by Morgagni in 1761; and in 1785 Hévin described in detail an operation for purulent appendicitis in the sac of a femoral hernia. Other cases were reported by Tritschler, in 1806, Hesselbach, in 1814, Taramelli, in 1835, Javanelli, in 1836, and a number of other early writers.

Merling in 1836, described a strangulated appendical hernia that was successfuly operated on by Tiedmann. Charyau, in 1837, and Cabaret, in 1842, also reported instances in which they had operated for hernia of the appendix. During this early period operation was undertaken only when an abscess had formed, and then the procedure consisted of simple incision and drainage.

From the middle of the nineteenth century, the operation was resorted to with increasing frequency, and with the advent of antisepsis it was undertaken earlier, but unless the appendix was gangrenous, it was reduced into the abdominal cavity. It was not until near the close of the last century that the removal of the appendix became a routine procedure.

VARIETIES

Inguinal hernia of the appendix is the most common form, constituting about fifty-five per cent. of all cases; forty per cent. are femoral; four per cent. umbilical; the remaining one per cent. being ventral, diaphragmatic and obturator.

The noninflamed appendix in a hernial sac is seldom diagnosed before operation. When the appendix is accompanied by the cecum or other viscera, it is usually healthy or only slightly diseased, because the hernial rings are necessarily large and the presence of the other viscera protect the appendix from pressure from the hernial ring, and adhesions to the sac wall do not form as often or as early as in isolated appendical hernia.

When the appendix is alone in the sac, the hernial ring is small and constriction sometimes occurs. In ninety-five per cent. of the cases of hernia of the isolated appendix, the appendix is adherent to the sac wall. Adhesions are more constant in this variety of hernia than in any other. The presence of adhesion and a narrow ring favor the early development of inflammation and infection. These complications are more frequent in femoral hernia, on account of the small femoral ring and the pressure and trauma produced by the movement of the thigh, than in inguinal hernia. Appendices in hernial sacs may be of normal length, four to five inches, but more often they are thickened and elongated, sometimes attaining a length of eight to twelve inches.

When hernia of the isolated appendix occurs in subjects with enlarged hernial rings and relaxed abdominal walls, it usually drags the cecum into the sac in a short time. When the appendix is in the hernial sac, it is more commonly subject to acute and chronic inflammation than when it remains in the abdomen.

Strangulated appendical hernia is rare. The term is often incorrectly applied to ordinary hernial appendicitis and this has led to much confusion. Appendicitis in the hernial sac has often been diagnosed as strangulated hernia, simply because the mass was irreducible and gangrenous, while in reality the same changes in an intraabdominal appendix would have been ascribed to inflammation and infection. I believe that most of the reported cases of socalled strangulation of the appendix are in reality hernial appendicitis.

Partial strangulation, which is very frequently the first stage of hernial appendicitis, is favored by the following factors: The dependent position of the appendix; the obstruction to the blood supply of the appendix, due to the weight of the cecum or other overlying viscera; the occasional pressure exerted by the edge of the hernial ring; and rarely, the presence of a fecal concretion or foreign body in the lumen of the appendix. The swelling, edema and congestion of the first stage, together with the increasing circulatory obstruction, lower the resistance of the appendix and provide the setting for the second stage, which consists of infection, followed by inflammation that terminates, as a rule in gangrene and perforation.

When the cecum or other viscera are strangluated with the appendix, the changes in the appendix seldom proceed beyond the first stage of edema and congestion. Complete strangulation of the appendix is rare, and almost always occurs when the appendix is the sole content of the sac. Nearly all of the recorded

cases have been in femoral hernias. In strangulated appendical hernia the sac usually contains fluid, which is clear, turbid or blood tinged. The appendix is dark in color, sometimes dusky or purple, and if gangrenous it may have a dead leaf hue, the same as strangulated intestine. The thick lymph associated with inflammation is absent and adhesions are not extensive. The point of constriction can usually be seen at the base of the appendix, or on the lower part of the cecum just beyond the cecoappendical junction. After the constriction is divided, a groove or furrow can often be seen at the point of strangulation and the appendix quickly assumes its normal color, just as other strangulated intestine does, providing gangrene has not set in.

The usual point of constriction is the rigid boundary of the hernial ring, especially the sharp edge of Gimbernat's ligament in femoral hernia. Sometimes the constriction is due to an omental band which is adherent to the sac wall; or to the neck of the sac being very narrow; or to a constriction in the sac itself.

When the mesoappendix accompanies the appendix into the hernial sac it soon becomes adherent to the sac wall or to the other contents. It is usually thickened, elongated and contains an excessive amount of fat, which increases the danger of strangulation by pressure on the appendix. When the mesoappendix is strangulated it has the appearance of intense venous congestion, resembling strangulated omental hernia.

RETROGRADE STRANGULATION

Retrograde strangulation sometimes occurs, usually when the appendix is abnormally long. The central portion of the appendix is caught in the hernial ring, while the tip and the base remain in the abdomen. The pressure at two points obstructs the blood supply and gangrene and perforation of the proximal end may develop rapidly.

AMOUNT OF APPENDIX IN HERNIAL SAC

The entire appendix is usually found in the sac of cecal hernias. Factors that favor the complete descent of the appendix are: An abnormally mobile cecum; a long mesoappendix; the absence of adhesions in the neck of the sac; and adhesion of the tip of the appendix to the testis, or to the fundus of the sac in complete hernia.

In a majority of the cases of hernia of the isolated appendix only one half to two thirds of the appendix lies in the sac. Incomplete hernias are usually caused by adhesions of the appendix to the neck of the sac, a short mesoappendix, an immobile cecum, and traction exerted on the appendix by the cecum. When the mobility of the cecum permits it to travel to the left side to a point opposite the left internal inguinal or femoral rings, it is an easy matter for the appendix to descend into a preformed sac. In left sided appendical hernias, the appendix is nearly always abnormally long, while in rightsided ones it is usually normal in length.

ETIOLOGY

Isolated inguinal hernia of the appendix is found most frequently in subjects under ten years of age. Hernia of the appendix and cecum is found most often in the middle aged or elderly, increasing in frequency as age advances. Femoral hernia of the appendix is most frequent between the fortieth and seventieth years. Inguinal hernia of the appendix nearly always occurs in males, and femoral appendical hernia in females.

The exciting causes of appendical hernia are the same as those that apply to other intestinal hernias, such as trauma, strain, lifting, coughing, whooping cough, and anything that increases intraabdominal tension. When the cecum enters the sac first, the hernia of the appendix is usually due to a long continued intraabdominal tension associated with a slipping of the parietal peritoneum, such as occurs in sliding hernia.

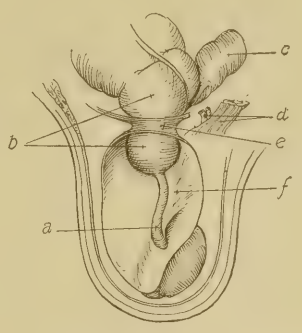

FIG. 1.—Appendicitis in the hernial sac: a, appendix; b, cecum; c, ileum; d, deep epigastric vessels and conjoined tendon; e, neck of sac; f, mesoappendix.

The predisposing causes of hernia of the appendix are: Abnormal mobility of the cecum; elongation of the mesentery and sometimes of the appendix; general ptosis of the abdominal viscera and relaxation of the abdominal wall; and traction exerted on the appendix by the cecum or adherent viscera already in the sac.

The same factors that are responsible for abdominal appendicitis are also the cause of hernial appendicitis. When the appendix enters the hernial sac it is subjected to more trauma and circulatory disturbances than when it remains in the abdomen, consequently it often becomes inflamed, its walls thicken, and it becomes adherent to the sac wall or to other viscera. In inguinal hernia the exposed position of the appendix and the contractions of the abdominal muscles are responsible for considerable irritation and trauma to the appendix. In femoral hernia, the narrowness of the hernial opening, the pressure exerted by the sharp edge of Gimbernat's ligament, and the trauma due to active movements of the thigh are responsible for the early development of appendicitis in a majority of femoral appendical hernias. The danger of strangulation of the isolated appendix is increased when the mesoappendix is thick and contains large lobules of fat.

As long as the hernia is easily reducible or can be retained by a truss, the patient is usually free from symptoms. As adhesions form between the appendix and the sac wall, he notices increasing pain and discomfort referred to the appendix region in the right hypogastrium, sometimes extending to the umbilicus or to the lower border of the ribs. Because of the small size of the hernia, the symptoms are usually referred to the appendix, and the possibility of a hernial appendicitis is generally overlooked. A correct diagnosis was made before operation in less than one per cent. of the cases reported in the literature.

In acute hernial appendicitis, other symptoms in addition to pain are: Distention of the abdomen with some tenderness, but without rigidity of the abdominal muscles such as is found in abdominal appendicitis; malaise, fever, constipation and disturbances in micturition. Flatus and feces continue to pass as obstruction does not occur unless small intestine,

cecum or colon is strangulated by the hernial ring. Sometimes there is pain referred to the scrotum in inguinal appendicitis; in the femoral variety the pain may be referred to the hip joint and down the inner side of the thigh as far as the knee. Movement of the thigh on the affected side is limited and often accompanied by considerable pain. In rare instances, there is a dragging pain referred to the right iliac fossa.

In hernial appendicitis the temperature is not as high as in abdominal appendicitis, on account of the localization of the infection within the sac, which is due to the early closure of the hernial opening by the inflammatory adhesions. Hence operation is usually delayed until after gangrene has developed. Shock and collapse are not marked except in children.

The signs of noninflamed appendix in the hernial sac are almost always vague and indefinite. In the beginning the hernia is small and easily reducible; as adhesions form in the sac, it becomes tender and painful, and more difficult to reduce. There is usually a history of occasional attacks of appendicitis, with the local symptoms referred to the hernia, which is temporarily irreducible.

The symptoms of hernia of the appendix so closely simulate those of other conditions, that diagnosis before operation is often impossible. In children the appendix can sometimes be palpated in the hernial sac, but very seldom in adults. There is often a history of a small reducible tumor, and sometimes there have been previous attacks of appendicitis, when the mass became temporarily irreducible. When inflammation develops, the tender, painful, irreducible tumor gradually increases in size, accompanied by the general symptoms and local signs of appendicitis. When the inflamed appendix accompanies the cecum, colon, omentum, or small intestine into a large hernial sac, the only symptoms of appendicitis may be those of hernial peritonitis.

TREATMENT

The operation is the treatment of choice for hernia of the appendix. The appendix should always be removed and never reduced into the abdominal cavity. If it cannot be removed through the hernial opening, because only a part of it is in the sac and adhesions and immobility of the cecum prevent its base from being drawn down into view, the incision should be extended upward through Poupart's ligament in femoral hernia, and beyond the internal ring in inguinal hernia.

If perforation or gangrene has developed or if an abscess has formed, the sac should be opened and any remaining portion of the appendix removed, the wound drained and the hernia repaired at a later time. In dealing with a gangrenous femoral hernia of the appendix, Schrager stitched the sac to the skin and converted it into a drainage tube.

If gangrene has extended beyond the tip of the appendix it is not safe to try to pull the appendix down to ligate it at the base. A better plan is to make a second incision, either a lateral rectus or a McBurney, and draw the cecum and appendix up into the wound and complete the operation as for abdominal appendicitis. When the appendix can be removed through the hernial opening, it is never advisable to anchor the stump to the neck of the sac; it should be pushed back into the abdomen and covered with a piece of omentum if the latter is available.

In retrograde strangulation only the central portion of the appendix is in the sac. The tip lies in the abdomen internal to the constricting ring, and it is nearly always gangrenous and often perforated, because the constriction obstructs its blood supply at two points. The ring should be enlarged and the tip exposed and removed with as little dissection as possible to avoid spreading the infection.

Proctostasis

H. STRAUSS, M.D.

Berlin, Germany

In addition to the etiological and anatomical considerations, the topical diagnosis is also of importance both in the questions of obstipation and in diarrhea. A superior and inferior portion of the colon can be differentiated on the basis of the nerve and blood supply. Such a classification may also be made for clinicodiagnostic purposes. At least the ascending colon and the descending colon and sigmoid, in addition to the rectum, clinically assume quite a characteristic and unique position also pathologically. I need only to call attention to typhlitis, typhloptosis, and typhlatony, on the one hand, and to the various well circumscribed diseases of the sigmoid, on the other, which show corresponding clinical sequelæ in anomalies of form and position, produced partly by inflammation and partly by constitutional factors. The hepatic flexure and the splenic flexure form a site of predilection for diseases. But the disease picture of proctostasis, proposed by myself some time ago, assumes a peculiar position, and that not in a topical direction alone.

Ever since I, in 1906, separated proctogenic obstipation—I so termed the affection at that time—from the large subject of obstipation, there have been added not only a number of other names (I mention only the slightly distinctive expression dyschezia of Hertz, which was also used in 1878 by Barnes for the conception of painful defecation, and which had therefore been applied for another purpose, and the expression torpor recti of G. Singer, which characterizes the nature of the affection much better) but also descriptions of the condition, which show disturbances have been included by some in the disease picture proposed by me, which have nothing in common with it. In order to show clearly that the disease picture has nothing to do with obstipation in

the stricter sense, but that it represents a special kind of disturbance of defecation, I myself have long ago replaced the term proctogenic obstipation by proctostasis.

I do not include in this conception those fecal stases in the rectum, that are produced, for example, by stenoses, fissure in ano, and other conditions. These changes bear their own peculiar names any way. At most, one could contrast them as symptomatic proctostasis with a genuine idiopathic proctostasis. Under the term proctostasis I include only that pathological condition, in which as a result of an anesthesia or hypesthesia of the nerves lying in the distal end of the rectum, the notification of the desire for emptying of the bowel does not reach the cerebrum or is not completed. The disease therefore consists of a blunting of the sensation of the scybala lying in the rectum and producing the stimulus for defecation.

SYMPTOMATOLOGY

Proctostasis is differentiated from Boas's fragmentary defecation by the fact that in the latter there is a more frequent desire for defecation, but not an anesthesia of the rectum: there is a stimulus present in the rectum, and not a weakened condition of the sensorium. This condition occurs not only in primary nervous diseases—especially neuroses—but far more often in patients with healthy nervous systems, who habitually repress their desire for stool for occupational reasons, faulty bringing up, and other causes. This disturbance is not rare if it is diligently looked for. To find it, it is usually necessary only to make a rectal examination. The finding of one or more large fecal masses with the simultaneous absence of desire for stools establishes the diagnosis.

The latter symptom is especially important, because even under normal conditions scybala may be found in the rectum at every defecation shortly before the expulsion of scybala. Under normal conditions these are experienced in the form of desire for stool. Röntgenographic examinations are not absolutely necessary for the determination of this disease picture, but they certainly reveal this very effectively. In slight and moderate grades of this disturbance the patients usually complain of only slight symptoms. These are limited usually to the sensations of pressure in the rectum and the symptom that appears striking to the patient, namely, that they have no desire for bowel evacuation. Occasionally slight signs of proctitis are also encountered. Sequelæ are usually avoided because the majority of the patients frequently go to the toilet from a feeling of duty. If this does not happen, or if there exists at the same time a weakening of the expulsive powers, quite unpleasant sequelæ may occur under certain conditions. The fecal masses may become hard, irritate the rectum and increase in size up to a giant mass as a result of the apposition of more feces with inflammatory products of the rectal wall. Such giant fecal masses, which have a waxlike and claylike consistency and are thereby differentiated from fecaliths in the stricter sense of the word, gradually produce a more or less severe and occasionally even hemorrhagic proctitis with frequent, usually small stools (socalled squirters), excruciating tenesmus, annoying sensations of pressure in the lower abdomen, and at times also pronounced dyspeptic symptoms, like anorexia, nausea, and gastric pressure, which can often undermine the state of nutrition considerably. In such cases one finds in the rectum a fecal mass ranging in size from that of an orange to that of small child's head and of the above described consistency, which can easily be rotated in the rectum because of their covering with mucus. Occasionally I have felt such a particular mass like a myoma from without above the symphysis, and in three cases there even resulted an extensive distention of the bladder as a result of compression of the urethra. Matthes also mentions a case of that sort.

PARADOX PROCTOSTASIS

In the course of time there may even occur a sigmoiditis, which liquefies the fecal masses coming from above as a result of the production of mucus, so that they can pass alongside of the fecal mass. This stage of the proctostasis, characterized by diarrheal conditions, I designated as paradox proctostasis in 1918. I have observed this paradox proctostasis almost exclusively in women with weakness of the expulsive powers. Most of these patients had been confined to bed for a long time for various reasons. In rare cases (I have observed such only twice) the fecal mass may act in the capacity of an occlusive obstruction, which produces an ascending retention of feces, so that symptoms resembling those of ileus finally occur as a result of colostasis.

THERAPY

The disease under discussion has a special practical interest also from the point of view of therapy. In the uncomplicated proctostasis (simple proctostasis), the change in the action of the rectum as a result of systematic education by the elimination of the centripetal process of inhibition is sufficient. At any rate, in the beginning a few enemas are necessary, but in paradox proctostasis enemas are not sufficient for evacuation of the fecal mass, because, on the one hand, the fecal mass is not hard enough to accomplish a passage through the anal canal when the pelvic flood is elevated by powerful expulsive movements, and, on the other, the patients avoid marked expulsive movements because of the pains produced by the inflammation of the rectal and anal walls in the attempted process of delivery. Therefore one is at first compelled to resort to a manual comminution and emptying of the mass after a preliminary application of a cocaine-belladonna-papaverin suppository, and possibly an injection of morphine. The escape is furthered by a few enemas. The crushed mass usually has a pronounced ammoniacal odor.

In the two cases of beginning ileus mentioned a surgical intervention had already been given consideration, but even in these cases the picture was changed almost immediately by the manual emptying and subsequent enemas. Diet, purgatives, and other measures usually recommended for the various forms of obstipation, are ineffective and therefore superfluous in the group of cases described. As aids intrarectal applications of electricity and vibratory massage may also be used, but it is most important that the disease be properly diagnosed and for this purpose a simple digital exploration of the rectum is usually sufficient.

The Selection of Operative Procedure in Carcinoma of the Rectum and Pelvic Colon

GEORGE ROBERTSON, F.R.C.S. Edin.
Dunfermline, Scotland

In making a decision upon the type of operation to be performed for the relief or cure of this disease many circumstances fail to be considered. Here, as in all cancers, the duration of the disease is extremely important. Advanced cancer of the rectum and pelvic colon can be treated by colostomy only, and in cases where obstructive symptoms arise colostomy must always be regarded as a necessary preliminary to further operation if possible. These obstructive cases belong to the late class. Colostomy as part of a radical procedure in the removal of an early carcinoma of the rectum and pelvic colon must not be accepted as so necessary as the textbook would have us believe. The possession of this unnatural anus has obvious disadvantages, and there are few patients so afflicted whose gratitude to the surgeon overflows.

For my part, in the light of my own experience and from the writings of well known contributors on the subject of operations for rectal cancer, I am now convinced that colostomy as a part of the radical operation is a rare necessity. The sacrifice of a large length of intestine above and below the site of the tumor seems to me unnecessary and destructive, and the more so when this is accompanied by a compulsory colostomy. A considerable section of gut and mesocolon, giving a good margin of safety, may be removed and an anastomosis performed between the divided ends. Such end to end union can be performed in nearly every case of early cancer of the rectum and pelvic colon. This disease usually remains localized and wonderfully quiescent for many months and it is rather extraordinary to note how near to the actual seat of the disease the gut can be divided and freedom from recurrence obtained.

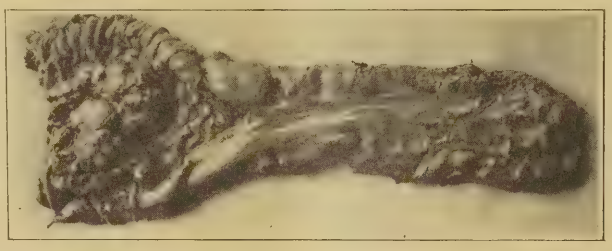

Fig. 1.—Showing the proximity of the gut section to the seat of the carcinoma (Case I).

In illustration of these statements the following cases are quoted. In each case the diagnosis was confirmed by microscopical examination at the Royal College of Physicians Laboratories, Edinburgh. Case I is illustrated to show the proximity of the gut section to the seat of the disease. (Fig. 1.)

Case I.—Miss M., aged thirty-five, had suffered for eight months from diarrhea and a frequent desire to defecate with some tenesmus.

By rectal examination, digital and sigmoidoscopic, the tumor was located in the gut above the line of reflection of peritoneum from rectum to vagina and uterus. Her pelvis had a narrow brim but a wide outlet; she was stunted in growth generally, had suffered from rickets in youth. As in female patients generally, if the cases are in the early stages the operation was easy and was undertaken by the posterior route with excision of the coccyx, but without a preliminary colostomy. Figure 1 shows the length of gut removed—the lower level of section is two and one half inches from the anal orifice, the upper level is not more than one half inch from the growing edge of the carcinoma. The pelvic colon was brought down from above and anastomosed to the rectal stump over a thick rubber drainage tube. Little shock attended the operation which was performed under a general anesthetic. Recovery was excellent. The operation was performed in 1914. She is alive and well and suffers no inconvenience in moving the bowels. I have examined her rectally at intervals during these eleven years, and could scarcely detect the line of bowel union. It must be conceded that if one half inch served as a safe margin on the proximal side of the disease, far too much gut was sacrificed below.

Case II.—Mr. T., aged fifty-eight, had complained of difficulty in moving the bowels for nearly a year. I saw him suffering from a definite degree of obstruction which passed away. He gave a history of several such attacks. The obstruction was located at practically the same point as in Case I. A preliminary colostomy was performed as low down as possible, because it was intended later to remove the gut almost up to the seat of the colostomy. The second part of the operation was done through a posterior incision with removal of the coccyx and small piece of the sacrum and the gut was removed almost up to the seat of the colostomy. The small blind piece of colon distal to the colostomy was simply closed up, sutured and the whole length of gut below, plus the anal canal and anus, removed. This operation was also performed eleven years ago. The patient is alive and well. Here as in Case I. perirectal tissue was ligatured and removed with the gut but no attempt was made to deal efficiently with possible glandular or lymphatic infection.

Case III.—Male, aged sixty. Duration twelve months approximately. Operated upon as in Case II. The patient was alive and well seven years after operation.

Case IV.—Female, aged fifty. Operation as in Cases II and III. Patient was alive and well twelve years after the operation. In these four cases the gut was divided at a point which seemed dangerously near the seat of the disease.

Case V.—Male, aged sixty. Duration of symptoms—bloody diarrhea—four weeks. Bimanual examination detected a small movable lump in the

pelvis. The sigmoidoscope revealed the tumor some distance above the peritoneal reflection from rectum to bladder. Operation through the left rectus sheath showed the tumor without peritoneal invasion about halfway between the brim of the pelvis and the bottom of Douglas's pouch. The superior hemorrhoidal vessels were ligatured in the mesocolon and the diseased section of the gut plus mesocolon were removed. Anastomosis was performed over a large rubber tube and after invagination and suture the free edge of the great omentum was lightly sutured to the line of bowel union. This patient was operated upon quite recently, and so far, the ease of procedure is the only thing worthy of comment. I feel quite sure, however, that he has as good a chance as the other patients of freedom from recurrence. To be free from recurrence without a colostomy is an extremely different matter to the patient than to be "cured" and have a colostomy. (Report on this case, Royal College of Physicians Laboratories, Edinburgh. Specimen: Tumor of rectum and glands of mesocolon showed carcinoma—no involvement of glands of mesocolon.)

I operated in a still more conservative manner recently upon an old lady seventy-six years of age when under spinal anesthesia. I exposed the ampulla of the rectum from behind, opened the gut by a longitudinal incision and excised an epitheliomatous area there as large as a crown piece. The gap was carefully closed by suture as was also the posterior incision in the rectal wall. A large rubber tube projecting into the rectum proximal to the seat of the operation was fixed by silkworm gut sutures to the perianal skin. She progressed favorably with no leakage from the rectal incisions. Her bowels moved well through and alongside the rubber tube fixed in the gut. Unfortunately, some weeks after operation she had a cerebral hemorrhage and died. It is contended that in all early cases, whether by the abdominal or by the posterior method, anastomosis of the bowel over a tube should be performed without preliminary colostomy and without extensive removal of healthy gut above and below the tumor. Thus a condition almost perfectly normal is obtained without undue risk of recurrence of the disease.

Suppurative Colitis

D. W. ZWEIG, M.D.
Vienna, Austria

The therapeutic results of the treatment of this most difficult form of the diseases of the colon depend largely upon the stage in which the disease comes for treatment. In the less severe forms, in which the general state of nutrition is more satisfactory, and the losses of blood and the suppuration are not too severe, an improvement in some cases and even a definite cure can be expected from internal or rectoscopic treatment. Only the severe cases are suitable for surgical intervention, and this for the reason that the results of the operative treatment are poor in severe colitis.

I have had only a few cases (I have operated in only ten cases), but the noteworthy part of this material is the fact that I have been able to keep these patients under observation for many years. Of these ten patients operated upon, three died from the operation. One patient died from peritonitis, the other two died from uncontrollable diarrheas. Two cases were definitely cured. In the one case an artificial anus could be closed after existing for two years, in the other after four years. Five patients remained uncured; they still have their artificial anus and the rectoscopic examination reveals that the ulcers in the rectum and sigmoid are still active.

As long as one cannot convince oneself by rectoscopic examination that all the ulcers have healed and that there is no blood or pus in the stools, one should not be deceived into attempting to close the artificial anus. A recurrence of the severe colitis is then almost certain. I do not by any means wish to draw any conclusions from this small number of cases operated upon regarding the percentage of patients cured and dead, but, according to my experience, I must say that this operation is a dangerous one and the definite cures are rare. At the same time I must also emphasize the fact that the operative technic can consist only of a total division of the colon at the cecum, so that one can with certainty prevent the feces from passing over the diseased mucosa. The formation of a fistula in the appendix or a mere lateral incision into the colon is futile. Directly after the operation I begin with the tiresome and time consuming treatment of the diseased mucous membrane of the colon. In order to avoid stenoses, daily irrigations with solutions of boric acid or potassium permanganate are just as important as the subsequent use of the bougie in the rectum.

My results from the rectoscopic treatment of this form of colitis are considerably more favorable. The following procedure has in my hands proved to be the most appropriate in many hundreds of cases. I have abandoned the preparation of the patients with irrigations, as every introduction of large amounts of fluid into the colon constitutes an injurious irritation and hinders the healing of the ulcers that are artificially stretched in this way. Therefore I also warn against the use of irrigations in every stage of severe colitis. I treat the patient every second day rectoscopically by the inflation of a powder mixture, of which the following combination has proved to be the most useful: dermatol, fifty, tannic acid and sodium chloride, each five, and stryphnon, ten. After the insertion of the rectoscope, the mucosa is thoroughly cleansed with cotton applicators and the powder is insufflated in sufficient amounts. A two per cent. silver nitrate solution may also be used instead of the insufflation of powder, but only in the cases in which the mucosa appears torpid and presents more the picture of atrophic colitis. One should particu-

larly be very careful with the use of silver nitrate and it requires great experience to know whether the mucosa can stand the irritating effect of the silver nitrate. If one begins with the silver nitrate solution too soon, severe recurrences frequently follow. If the rectoscopic treatment is not possible for external reasons, I allow the patient to use only dermatol suppositories (0.5 gram three times daily) or dermatol—oil enemas (5.0 grams dermatol to twenty c. c. oil) at home.

In conclusion, I take the liberty of demonstrating a rectoscopic case made for me, and which contains all the instruments necessary for the diagnosis and treatment of rectal diseases. It contains three rectoscopic tubes of different diameters, the panelectroscope of Leiter, which provides an exceedingly intensive source of light from without, two applicator forceps, a balloon insufflator, a syringe for the rectoscopic irrigation of the mucosa with silver nitrate solution, and all the necessary accessory instruments.

Additional Remarks on Cholecystography

MAX EINHORN, M.D.
New York

In a paper by W. H. Stewart, E. J. Ryan, and myself, read before the American Gastroenterological Association on May 26, 1925, I gave the following summary: "Cholecystography (according to Graham) has found a permanent important place in medicine. The intravenous injection of tetrabromphenolphthalein is frequently accompanied by reactions, which at times are of a severe type. . . . The administration of tetraiodophenolphthalein by mouth or jejunum, not in large doses, is accompanied by fewer reactions, and is therefore preferable to the intravenous method."

In the same paper the authors also mentioned that no strong cathartics nor too much fasting should be employed shortly before using cholecystography, as these severe measures are apt to increase the unpleasant reactions frequently following the application of the tetraiodo salt.

Of fifteen new cases of gallbladder and digestive diseases, in which the Graham test was done according to the above mentioned rules, and the tetraiodo salt given through the duodenal tube, I have selected five for special discussion regarding cholecystography. To these will be added one case of gallbladder pathology observed at the same time, without cholecystography, in order to show the great value to the patient of a correct mode of procedure.

All the cases which will be described in this paper have been treated by me during the months of May, June, and July, 1925. It is, thus, seen at a glance that we deal here, not with rare conditions, but with common everyday afflictions. This adds to the importance of the subject in question. Permit me to describe these few cases seriatim, according to the time they were treated.

Case I.—May 7, 1925. Peptic ulcer and hydrops of gallbladder, due to cystic duct occlusion by a biliary calculus. Mrs. L. R., forty-six years old. Patient complained of attacks of severe pain in the epigastrium several hours after meals. Vomiting relieved the attack. At first the attacks occurred principally after heavy meals, and the patient would be free for weeks at a time. Later on the attacks became more frequent and severe, mostly when in the recumbent position, especially at bedtime. The patient often awoke in the middle of the night with severe pain. There was never any pain in the morning. Since youth she had had frequent attacks of heartburn and vomiting, with an acid taste. In 1905 the patient had puerperal fever. Headaches commenced to trouble the patient as soon as her digestive trouble set in. About three weeks ago there was vomiting of brownish blood. The stool was sometimes tarry black. The patient was frequently constipated.

Present condition: Stomach dilated. X ray: six hour retention. Gastric contents: free HCl=84; Ac.=102. Urine, specific gravity 1.008; albumin +, no sugar. Hemoglobin 80 per cent., red blood corpuscles 5,400,000; white blood corpuscles 7,400; polynuclears 66 per cent. D. B., May 8, 1925. Blood stain 51-54, bile 60 to end. The direct examination of the bile on May 19th showed: dark yellow brown, turbid; mucus. Microscopically—bunchberry and cholesterin crystals. The diagnosis was peptic ulcer and cholecystitis. Duodenal alimentation May 11th to 26th. During alimentation the patient felt fairly comfortable. So soon, however, as nutrition by mouth was resumed, patient began to complain of some discomfort. On May 29th there was an attack of pain requiring the hypodermic injection of morphine and a slight rise of tempertaure, 99.8° F.; on the 30th, 100.5°, May 31st, 99.0°. At this time there was distinct tenderness in the right hypochondrium. The blood showed leucocytosis of 11,000.

An acute exacerbation of an old cholecystitis in the nature of an empyema or something akin to it was diagnosed, and an operation recommended. The patient was too sick to be subjected to the Graham test. Besides, the diagnosis appeared to be well established. On June 3rd, Willy Meyer, after arriving at the conclusions just stated, performed the operation. A big stone was found in the cystic duct, occluding it completely. The gallbladder was considerably enlarged, walls much thickened, containing a slimy fluid without bile. Microscopically the fluid showed amorphous material and cholesterin crystals. A cholecystectomy was done and the patient made an uneventful recovery.

Case II.—Cholelithiasis with cardiospasm and pylorospasm; empyema of the gallbladder, with perforation in newly formed adhesions. May 17, 1925. William F., forty years old. The patient complained of epigastric pain two to three hours after meals, radiating in the back, and lasting a few hours, for the last three years. For the last two months the

patient experienced severe pain below the ensiform process immediately after and even during the meals. There was no vomiting. The patient complained a great deal of heart burn and acid taste in the mouth, also weakness and dizzy sensation. The bowels moved regularly. On account of the pain, the patient was afraid to eat and experienced difficulty in taking even the lightest foods. He lost thirteen pounds in weight during the last month. The patient had pneumonia and appendicitis twenty-five years ago.

The patient looked greatly cachectic. The chest organs were free. A swallowing sound was absent. A bougie (48 F.) encountered slight resistance at cardia and passed into the stomach. The liver was enlarged, extending three fingers below the costal margin in the right mamillary line. The stomach was dilated, extending to the symphysis pubis. Gastric contents: HCl=50; Ac.=60. String test, May 18, 1925. Bile stain trace at end; length of string 65 cm. Duodenal contents, fasting: May 29, 1925, light yellow, slightly turbid, after standing in the air becomes grey and more turbid. Alkalinity=35; A=10; S=2; T=3. Microscopically: some cholesterin crystals and bunchberry crystals, also pus corpuscles. Blood and urine showed nothing abnormal and the Wassermann reaction is negative. An x ray examination of the gastrointestinal tract showed a dilated and prolapsed stomach and six hour gastric retention.

Taking into consideration the difficulty in eating (even milk), the absence of the swallowing sound, the permeability of the cardia and pylorus to instruments, the turbid state of the bile and the gastric retention, a diagnosis of cholecystitis with secondary cardiospasm and pylorospasm was made.

By means of the pyloric dilator the pylorus and cardia were stretched in the retrograde way. The purpose of this was twofold, 1, to show that there was no real organic lesion at either of these openings, and 2, to exert a beneficial effect for the passage of food through these outlets. The patient being in a high state of malnutrition, it was thought best to institute duodenal alimentation, in order to give the patient adequate nutrition. The duodenal tube was introduced, and the patient nourished through it, as soon as it had reached the duodenum. In about ten days the patient showed an increase in weight of five pounds. He looked and felt very well.

The liver was now much less swollen. At this period the patient had a severe attack of pain in the right hypochondrium, requiring morphine by hypodermic injections. Upon examination a swelling beneath the liver was distinctly palpable, which was painful on pressure. Although clinically the resistant mass appeared to be the gallbladder, all other means of examination were used in order to make the diagnosis more definite. A barium enema allowed the x ray to show the colon in normal state. The Graham test for cholecystography was employed. No gallbladder shadow could be obtained. This negative result was taken to indicate an occlusion of the cystic duct, probably by a stone.

After a consultation with Franz Torek, who agreed with me, it was decided to operate. The operation was performed by Torek on June 6, 1925. The gallbladder was found enlarged and thickened and imbedded in adhesions. These were separated from the gallbladder, which was bluish grey in color. Some dark grey material escaped during this procedure through a perforation. The gallbladder was tied off at the cystic duct and extirpated. Two stones were found in the gallbladder, one occluding the cystic duct, the other lying in the fundus and separated from the former by tissue. The gallbladder when opened contained pus and dirty material. Microscopically the gallbladder bile contained many cholesterin crystals. The patient made an uneventful recovery and can now eat any ordinary food with impunity.

The x ray picture (Fig. 1) shows the size of W. F.'s gallbladder, imitated by gauze) and the relation of the two stones to each other.

Case III.—Cholelithiasis with digestive disturbances, hydrops of gallbladder due to cystic duct obstruction. Mrs. J. A. C. July 10, 1925. The patient had always been well until fifteen months ago, when she began to be troubled with digestive disturbances. At the time the patient had taken care of her very sick mother. She ascribed her ailment as probably due to overanxiety and overstrain. The patient would have attacks of heartburn and distress in the epigastrium lasting two or three days, and then she would feel comparatively well for a month or so, when a new attack would appear. There was never a severe attack of colic present, nor did the patient ever require a hypodermic of morphine. The patient lost about fifteen to twenty pounds in weight and a great deal in strength, not being able to fulfil her social duties. She also became constipated.

The physical examination did not show anything abnormal in the chest. The stomach was slightly prolapsed, the liver not enlarged. The gastric contents revealed: HCl plus, acidity=65; no blood. The duodenal bucket string test showed bile at the end of the string and no blood. The direct examination of the bile in the fasting condition showed: dark yellow, turbid; alkalinity=20; A=2, S=1, T=1. Microscopically: numerous cholesterin—calcium bilirubin—and bunchberry crystals; bacteria and mucus. After five per cent. peptone, slight color reaction was present, beginning at ten and ending at twenty-two minutes after the instillation. Total flow in thirty-eight minutes, seventy-five c. c., the amount of darker bile being thirty c. c. The Graham test showed a shadow, probably representing stones and a very indistinct shadow of the gallbladder (Fig. 2). Temperature, urine, and blood without any anomalies; stool negative for blood.

After a consultation with E. Cowan and Franz Torek, we all agreed that the diagnosis was that of gallstones, causing secondary digestive disturbances, and that an operation was indicated.

The operation was performed by Torek on July 20, 1925. The gallbladder was found thickened and enlarged, half the size of a man's fist. On palpation a stone could be palpated in the neck of the gallbladder and also in the cystic duct. Otherwise, in the fundus of the gallbladder, which was very tense, nothing could be palpated. There were merely a few adhesions near the neck of the gallbladder to the liver, otherwise it was free. The gallbladder and appendix were removed. Upon opening the gallbladder there was no bile in it, but seventy peasized stones and a mucopurulent fluid without any bad odor, were found in it. In the fluid sandy looking yellowish and

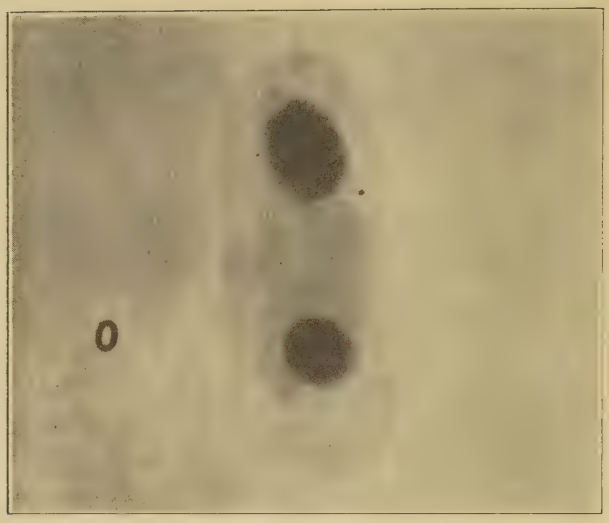

Fig. 1.—X ray photograph of the gallstones of William F. (Case II), and the relation of their position to each other in the gallbladder (the latter imitated by gauze).

greyish masses were discovered. The mucosa of the gallbladder was thickened and ecchymosed in parts. Microscopically: cholesterin crystals, mucus, and bunchberry crystals.

The patient made an uneventful recovery and now eats ordinary foods without any inconvenience.

Case IV.—Cholelithiasis with grave secondary gastrointestinal symptoms. July 17, 1925. Mrs. M. E., sixty years old, used to weigh about 150 pounds. In July, 1924, she began to feel badly, and suffered from frequent loose bowel movements, varying from one to ten daily. At the same time she lost considerably in weight. She never vomited nor did she have pain, but she felt extremely weak. These symptoms persisted until March, 1925, when the patient felt much better, having one movement a day, and increasing in weight up to 138 pounds. In April the patient went from Spain to Cuba, and while there she experienced a return of her trouble, frequent diarrhea, weakness, and loss in weight. Beginning in July, she weighed only 120 pounds, and came to New York for treatment. She had frequent diarrheal movements and great weakness.

On examination the patient looked pale. The stomach extended to about one or two fingers' width below the navel. The liver was not enlarged. The gastric contents showed: HCl=none; acidity=25; rennet, plus, no blood. The string test showed bile at the end of the string and no blood. The stool was negative for blood; the urine normal. The blood showed signs of secondary anemia.

The duodenal contents examined in the fasting condition on July 17th showed: light yellow, slightly turbid; blackish and brownish particles. Alkalinity=20, A=10, S=3, T=4. Microscopically the particles consisted of calcium bilirubin and numerous cholesterin crystals. After five per cent. peptone, good color reaction began at ten and ended at twenty minutes after instillation. The total flow was 40 c. c. in twenty-six minutes; the dark bile amounting to twenty five c. c. The digestive test capsule was recovered in the stool after nineteen and one half hours. Everything had disappeared excepting fat and thymus, but there were no nuclei present. An x ray of the stomach showed an abnormal sacculation of the fundus, but *no* real defect. The Graham test failed to show a gallbladder shadow.

Based principally on the findings of the direct examination of the bile and supported by the result of the Graham test (which gave *no* gallbladder shadow) a diagnosis of cholecystitis with stone (probably in the cystic duct) was made. In view of the grave symptoms of the patient an operation for removal of the gallbladder and a thorough exploration of the abdominal cavity was recommended.

The operation was performed by Torek on July 24th. The anterior end of the spleen was pointed instead of being rounded. (This might have accounted for the deformity of the stomach found by the x rays.) The omentum was firmly adherent to the gallbladder, and the latter was adherent to the liver. The gallbladder was not much enlarged, nor thickened. In the fundus an elongated oval stone (Figs. 3 and 4) could be felt. The gallbladder (fundus) appeared to be divided into two portions as if having an hourglass contraction at the end. When the gallbladder was opened a big stone, the size of a pecan nut, was found. The mucosa was congested. There was an opening leading to another division of the fundus. The cystic duct was free. The bile was tarry looking. Microscopically: many cholesterin crystals, few calcium bilirubin, and bunchberry crystals. A cholecystectomy was done. The patient made a rapid recovery.

Case V.—Tumor of pancreas of doubtful character, causing common duct obstruction with jaundice. Gallbladder immensely dilated and thickened. July 22, 1925. Jacob G., fifty-six years old, began to complain of indigestion and gastric distress in 1919. The patient had to resort to large quantities of bicarbonate of soda to get relief. For the next few years the symptoms mentioned would appear oft and on for a few weeks, with free periods of intermission in be-

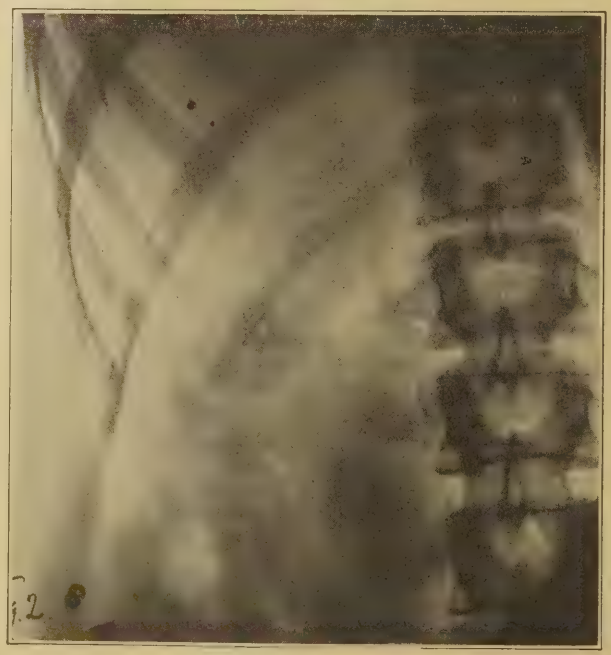

Fig. 2.—X ray photograph of Mrs. J. C. (Case III) after instillation of sodium tetraiodophenolphthalein into the duodenum. A sharp shadow consisting of several round bodies is visible in the gallbladder region, in the same area a faint outline of gooseegg size is noticeable. Scantily visible shadow of the gallbladder, with a distinct accumulation of stones therein.

tween. The pains were never very severe. The patient weighed 160 pounds when his trouble commenced. Three months ago the patient began to suffer more severely. The pain became more acute, the appetite disappeared almost completely, and the patient lost considerably in weight. For the last six weeks the patient became jaundiced. There were no attacks of colicky pains in the upper abdomen, nor any rise of temperature. When admitted to the hospital on July 23, 1925, the patient's weight was 113 pounds.

The patient looked greatly emaciated and distinctly icteric. Thoracic organs were normal, with the exception of the heart which was slightly dilated to the right. The abdomen was soft and somewhat caved in. The stomach extended to the symphysis (splashing sound). The liver was enlarged, overlapping the right costal margin by two to three fingers' width. A soft resistant mass of oval shape stretching beneath the border of the liver of hen's egg size could be easily mapped out. The urine contained bile and urobilinogen, no albumin or sugar. The blood showed some anemia and leucopenia. Wassermann, ++. The gastric contents showed: HCl+, Ac. 105, no blood.

X ray of stomach showed slight six hour retention and lack of peristalsis at the pyloric portion of the stomach. The duodenal bucket string test showed a trace of bile at the end of the string, no blood. The duodenal contents examined in a fasting condition on July 25th showed: 15 c. c. light yellow, neutral, containing several blackish particles. Microscopically: cholesterin and bunchberry crystals; big conglomerations of cholesterin crystals; a few pus corpuscles and epithelial cells. After sixty c. c. of five per cent. peptone, no bile; all specimens acid, two containing free HCl. Microscopically: many bunchberry crystals, few cholesterin crystals. The Graham test failed to show a gallbladder shadow. As to diagnosis, the gradual development of jaundice without attacks of colic made me think of a possible neoplasm of the gallbladder, while the long history of disease and the findings of the direct examination of the bile seemed to favor a benign condition.

Before resorting to an operation which was indicated, it was decided to improve the general condition of the patient by duodenal alimentation and instillation of fluids; for, otherwise, the patient was in too weakened a condition to stand the strain of surgery. The patient improved quickly under this régime, and on July 29th Franz Torek performed the operation. The gallbladder was found to be three quarters the size of a man's fist, intensely filled with a dark black tarry bile. The pancreas was hard and nodular; the duodenum not movable; firmly connected with the pancreas; no stones palpated in the common bile duct. The cause of the obstruction was the pancreas. A cholecystgastrostomy was done.

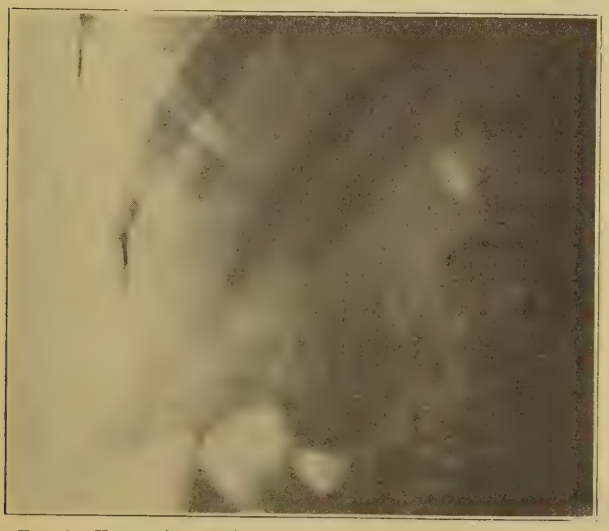

Fig. 5.—X ray picture of the gallbladder of Mrs. E. N. (Case VI) after duodenal instillation of 0.75 grams of sodium tetraiodophenolphthalein. Notwithstanding the small amount of the tetraiodo salt, the gallbladder is distinctly visible.

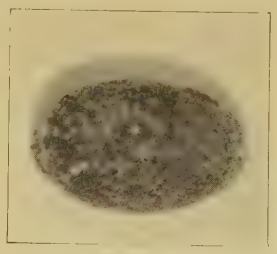

Fig. 3 A

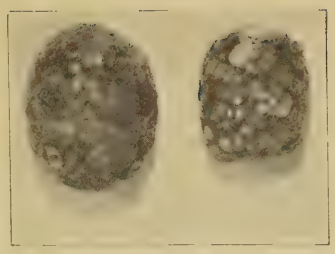

Fig. 3 B

Fig. 3.—A. Mrs. L. R., July 3, 1925, operated upon by Willy Meyer. Large stone in cystic duct; gallbladder enlarged, thickened, containing slimy fluid without bile. Graham test not made. B. W. F. July 5, 1925, operated upon by Franz Torek; two big stones found in the gallbladder, one occluding cysticus; gallbladder enlarged, thickened, containing pus; gallbladder had perforated into adhesions. Graham test showed no gallbladder shadow. Illustration, natural size.

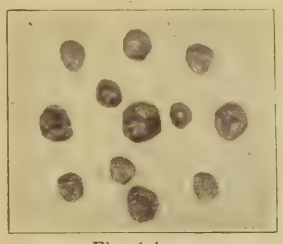

Fig. 4 A

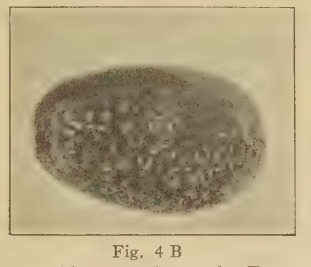

Fig. 4 B

Fig. 4.—A. Mrs. J. A. C., July 20, 1925, operated upon by Franz Torek; gallbladder enlarged, thickened, containing no bile, but mucus, sand, and stones (about seventy peasize) one in cystic duct occluding it. Graham test: stones visible, gallbladder shadow not distinct. B. Mrs. Margarita E., July 24, 1925, operated upon by Franz Torek; big stone in gallbladder, bile tarry, not very turbid; cysticus free. Graham test: no gallbladder shadow. Illustrations, natural size.

Examination of the bile aspirated from the gallbladder during the operation showed an alkalinity—90; specific gravity—1040. Microscopically: amorphous bunchberry and occasional closterin crystals; some calcium bilirubin crystals; no bacteria. The tube was left in place during the operation and alimentation resumed through it the day following. The patient stood the operation nicely and was recovering when he was seized by pneumonia and succumbed.

Case VI.—Gastric ulcer and chronic cholecystitis. July 15, 1925. Mrs. E. N., about forty years old, complained of gastric distress and incessant eructations for two to three years. The string test showed a blood stain on the string not far distant from the cardia. The bile examined in the fasting condition showed: yellow, turbid, alkaline, contained several small blackish particles, which microscopically showed to consist of mucus, calcium, bilirubin, and bunchberry crystals.

The diagnosis was gastric ulcer and chronic cholecystitis. Duodenal alimentation gave the patient much relief. The Graham test was done, with 0.75 of the sodium tetraiodophenolphthalein, as the patient vomited the tube after the installation of the above solution. The gallbladder, however, was distinctly visible, even with this small amount. (Fig. 5.)

REMARKS

In reviewing the cases just described, we find the first three dealing with distention and thickening of the gallbladder of a serious type. In one of these there was perforation of the gallbladder wall in the freshly formed adhesions (Case II, W. F.); in the other two, hydrops. In all three there was cystic duct obstruction caused by a biliary calculus. In two of these, in which the Graham test was done, cholecystography showed in one *no* gallbladder shadow whatever, and in the other, an accumulation of stones in the gallbladder area and a very faint outline of the vesicula fellea, not as sharp by far as would be usually encountered in ordinary gallbladders. This failure to obtain a gallbladder shadow would be expected in cystic duct obstruction, for the bile carrying the tetraiodo salt cannot enter the gallbladder. The faint outline in one is due to some of the salt reaching gallbladder walls by way of general circulation.

Case IV (Margarita E.) deserves special mention. The course of the disease was very irregular. There were clinically no symptoms of cholecystitis present. The direct examination of the bile gave positive findings. The Graham test (no gallbladder shadow) appeared to speak for stone in the cystic duct or for some other form of occlusion of this outlet. In view of the possibility of malignancy, an operation was indicated. At the operation the diagnosis of cholecystitis with probable stone was found correct, but the assumption of occlusion of the cysticus (by a calculus) was not correct, the cysticus being perfectly free. How to explain the failure of entrance of the sodium tetraiodo into the gallbladder—excepting by a spasm provoked by the calculus lodged in the fundus—is difficult to say. It is, however, of great import to know that such cases occur.

Case V (Jacob G.) of tumor of the pancreas with jaundice, caused by common duct obstruction with an immensely dilated and thickened gallbladder filled with stagnant bile, failed to give a shadow by the x ray after the Graham test. Inasmuch as the cysticus was free, we would, at first thought, think that a gallbladder shadow should have been produced here. Taking into consideration, however, the high degree of bile stagnation in the vesicula fellea so that the latter was filled to its maximum and not a drop of fluid could enter it, the liver bile carrying the tetraiodo salt had to go back to that organ and from there to the general circulation. It is natural that even without a real closure of the cysticus, the gallbladder could not be shown by the Graham method.

Case VI (Mrs. E. N.) has been cited, in order to show how small a quantity of the sodium tetraiodophenolphthalein given by the duodenal tube is at times sufficient to render the gallbladder visible to the x rays. The amount given in this particular case was 150 c. c. of a one half of one per cent. solution of sodium tetraiodo, or 0.75 gm. of this salt.

In conclusion, this paper seems to show the comparatively frequent occurrence of severe gallbladder lesions, the help we derive for the recognition of these ailments from the clinical history supplemented by the usual methods of examination in conjunction with the direct examination of the bile and the Graham test, and ultimately the great benefit in these cases of appropriate surgery. With regard to cholestography, there must be a fresh flow of bile entering the gallbladder, in order to make it feasible. When this is not the case, no matter whether due to cystic duct occlusion or to other causes, there may be at times a faint outline of the gallbladder obtainable, but never a real good picture.

20 East Sixty-third Street.

The Differential Diagnosis Between Cancer and Other Gastric Conditions Essentially Associated with Subacidity*

SEYMOUR BASCH, M.D.
New York

The importance of a correct diagnosis of gastric cancer is so thoroughly appreciated by the lay and professional world that discussion of this point is unnecessary. While, however, a typical advanced case is readily recognized, the definite diagnosis of early and of moderately advanced gastric cancer is at times difficult and even impossible prior to operation or autopsy. Often, too, noncancerous conditions are mistaken for cancerous, and since the prognosis in the former, when properly treated, is almost invariably more favorable than in the latter, the importance of differentiation is obvious.

These pseudocancerous conditions are very numerous and it is manifestly impossible to consider them all in a brief presentation. I have, therefore, chosen for this discussion one of the most important intragastric groups, namely, those diseases that have as an integral part of their clinical picture a deficient or subacid state of the gastric juice. It is well known that not all gastric cancers are accompanied by subacidity: a rather considerable proportion, during their early stages at least, show a normal or even very high amount of hydrochloric acid upon test meal examination. Nevertheless, the classical conception of cancer includes a diminution and subsequent disappearance of normal acidity and its later replacement by lactic and other organic acids. This is the type of cancer referred to in the present paper. The rapid diminution of the gastric secretion is most probably due to the fact that cancer originates in the epithelial or glandular elements of the stomach, and is very early associated with an infiltrating gastritis, thus adding catarrhal products to the cancerous ones. In the leather bottle, and other extensive sclerotic types of gastric cancer, a complete achylia is present.

*Read before the Section on Gastroenterology and Proctology at the Seventy-Sixth Annual Session of the American Medical Association, Atlantic City, May, 1925.

To aid in distinguishing between the subacid type of cancer and other subacid gastric conditions later to be named, it is necessary first to discuss briefly the chief clinical manifestations of this form of gastric cancer.

SUBACID TYPE OF CANCER

It is an affection of middle or advanced life with a continuous and rapidly downward clinical course. Usually there is no history of previous gastric complaint, though not infrequently a precancerous suggestion of ulcer, or, more rarely, of gastritis, is obtainable. Gastric cancer is characterized by very marked decrease in appetite, weight and strength, by anemia and cachexia, by gastric distress or pain, not necessarily associated with meals, and by vomitus or stomach contents showing diminished or absent hydrochloric acid, which is frequently replaced by lactic and other organic acids. The stomach contents often also contain blood, excessive mucus and decomposition products, together with stagnant masses and foreign microorganisms. Occasionally, tumor fragments are found in the vomitus or the lavage water, especially in the softer types of the growth. As a rule, the tongue is heavily coated, the breath foul and the gums in poor condition. With the occasional exception of Virchow's gland in the left supraclavicular region, it is rare to find any palpable enlarged surface lymphatic glands.

TYPICAL GASTRIC CANCER

In advanced typical gastric cancer the abdomen is sunken and readily palpated. Inspection and palpation reveal a more or less extensive tumor mass in the stomach area. This mass is hard and irregular in shape; its surface may be smooth or nodular, and it is usually tender to the touch. Depending upon its situation and other associated factors, the tumor may or may not move with respiration and digital palpation. It should, however, be remembered that even a very large and inoperable growth in the socalled silent area of the stomach, i. e., behind the left lobe of the liver, may elude most careful palpation even under general anesthesia. Here the diagnosis must rest upon the history and the physical condition of the patient, together with the laboratory and röntgenological findings.

SCLEROSING TYPES OF CANCER

In the sclerosing types of cancer the walls of the stomach are very much thickened and hardened and the entire organ shrunken in size with an almost obliterated lumen and a patulous pyloric orifice. The stomach, therefore, in these cases presents a very hard tumor mass, whose contents are small in amount and rapidly pass into the duodenum without detectable peristaltic action. In cancer involving the cardiac opening, the stomach generally is also markedly decreased in size. Tumors at the pylorus are as a rule associated with mechanical obstruction and secondary dilatation of the stomach. Here there is not only the tumor mass itself, but also the well known manifestations of gastrectasia, namely, greatly enlarged stomach outlines, more or less visible and palpable peristaltic overactivity (socalled peristaltic stiffening), splashing sounds, gurgling, retained stomach contents in the fasting state, massive vomiting, and other symptoms.

EXAMINATION OF THE BLOOD

Parallel with the progress of disease there develops a secondary anemia, which, in advanced cases is so profound as strongly to suggest the primary pernicious form of anemia. Thus far, all investigations for the discovery of something in the blood specific for cancer have proved disappointing. On the other hand, the discovery that gastric cancer yields a protein digesting ferment has led to the introduction of the Salomon and the Wolff-Junghans tests for the differential diagnosis between malignant and benign achylias. The latter test for soluble albumen is especially valuable and should be better known and more frequently employed. It is easily carried out, inexpensive and requires but little time. Smithies (1) found it positive in eighty per cent. of 230 cases of operatively or pathologically demonstrated gastric cancers. Friedenwald (2) and others have also found this test most serviceable.

RÖNTGENOLOGICAL EVIDENCE

The scope of this presentation precludes a detailed discussion of the röntgenological diagnosis of gastric cancer. Medical literature is flooded with such descriptions. Undoubtedly röntgenology has proved of immense value in this connection, often revealing the presence of a tumor not distinguishable through other clinical methods. This applies more particularly to lesions involving the orifices and curvatures. Here, in the nonulcerous type, the rays are very dependable in the early as well as in the late stages of the disease. In central cancer of the fundus, especially of the posterior wall, they cannot always be depended upon, for not infrequently they fail to show early and even late tumors located there. Often, too, exploration reveals a far greater extent of the growth than indicated by the röntgenological examination. Positive evidence in early or doubtful cases always calls for exploratory laparotomy. Where negative röntgen ray findings contradict strong clinical and laboratory evidence, the patient ought to be kept under close supervision and control. Unless there is a speedy improvement he should be surgically explored.

DIFFERENTIAL DIAGNOSIS

The data already mentioned as associated with a typical advanced case, are, taken collectively, so characteristic that when for the most part present, the diagnosis is readily made. Frequently, however, a few or even most of the characteristic data are absent, and it may be impossible at the time to establish a correct diagnosis short of laparotomy and histological examination of any presenting tumor. The great importance of the histological examination cannot be sufficiently emphasized. There is so much at stake concerning the prognosis, the correct operative procedure, and, not infrequently, the real diagnosis of the diseased condition, that a histological examination should always be demanded. Instances can be multiplied where the operative diagnosis of cancer, based upon the presence of a very hard and large tumor mass, was refuted by the subsequent career of the patient, or by the report of the histologist or serologist. On the other hand, exploratory and postmortem examinations have sufficiently often disproved the presumptive diagnosis made by the internist of an "unquestionable case of cancer of the stomach."

For the purpose of simpler discussion the differential diagnosis will be considered under two headings, namely, 1, conditions in which a tumor mass is present, and 2, those in which there is no tumor mass present. The first division includes sarcoma, benign tumors, tuberculosis and syphilis; the second chronic gastritis, benign functional achylia and pernicious anemia. Gastric ulcer is omitted because hyperacidity and not subacidity is an integral part of its clinical picture. A detailed discussion of its differential diagnosis has been published elsewhere by me (3).

CONDITIONS IN WHICH A TUMOR MASS IS PRESENT

The presence of a tumor mass, definitely proved to be gastric, is the most important physical sign of gastric cancer. When associated with marked emaciation, cachexia and the characteristic laboratory and x ray findings, the diagnosis becomes almost a certainty. It should be borne in mind, however, that any variety of intragastric tumor and also some extragastric ones that cause pressure upon the stomach, can give rise to almost identical physical phenomena, so that a differential diagnosis may be extremely difficult or even impossible, without resorting to exploratory incision or autopsy. Even in the last eventuality, we may, as already pointed out, have to await a histological determination.

Sarcoma.—This is considered very rare, but must occur far more frequently than the records tend to show. Many cases diagnosed as carcinoma undoubtedly are sarcoma. Thus Perry and Shaw (4) through later histological investigations of a series of fifty cases classified in Guy's Hospital as cancer, proved that four of them were really round celled sarcomas. Statistics indicate that primary sarcoma seldom attacks the stomach before the fourth decade of life and most frequently between the ages of fifty and sixty. It is a much more slowly growing neoplasm than cancer and in relatively early cases offers a far better chance for radical cure.

Unfortunately there are no definite diagnostic criteria even for a far advanced gastric sarcoma. Correct diagnoses have only been made through operation, or preoperatively through histological examination of tumor particles found in stomach contents, or perhaps through excision of a metastatic growth in the rectum, skin, glands, etc. (5).

Gastric cancer and sarcoma have many characteristics in common, such as the earmarks and accompaniments of malignancy, the alterations in gastric structure and functions, the occurrence of hemorrhages, metastases, splenic tumors and febrile states. Since sarcoma, however, arises from the nonepithelial or intramural tissues, the mucous membrane is usually not involved or, if so, only secondarily through pressure or erosion. Secretory disturbances are, therefore, more typical of cancer and are not among the diagnostic criteria of sarcoma. Cancer is more frequently located at the orifices and in the body of the stomach, sarcoma oftener along the curvatures; hence cancer is more apt to be associated with stenosis. Pyloric obstruction, when present in sarcoma, is usually a late complication and due to massive infiltration of the stomach walls rather than to a real pyloric stenosis. According to Haudeck (6), sarcoma spreads flatly throughout the walls of the stomach and does not project into its lumen; it therefore causes no filling defect and presents no visible radiological indentations. In other words, the stomach presents a smooth and rigid wall and a wide lumen.

Benign tumors.—These are relatively infrequent, but probably less so than is generally assumed. I have encountered four cases, three of which were preoperatively diagnosed. Eusterman and Gentry (7) reported twenty-seven cases observed in the Mayo Clinic between 1907 and 1921, being 1.3 per cent. of the 2,168 gastric tumors that came to operation there during that period of time. This does not, however, indicate the actual ratio between benign and malignant gastric tumors, for many other malignant cases were inoperable, while other benign tumors were undoubtedly regarded as malignant ones and declined operation or were refused as inoperable.

Benign tumors are included in the present discussion, because they are frequently associated with achylia, marked dyspeptic symptoms, slight or severe hematemesis or melena, pain, profound anemia and loss in weight. Often a palpable tumor is present. Thus, we have a clinical picture that strongly suggests and frequently has been diagnosed as gastric cancer. In addition, the radiological examination reveals a shadow defect that appears to confirm this diagnosis and often has been so reported.

Undoubtedly these tumors may remain quiescent for many years, and not infrequently become clinically active during the cancer years. When situated in the pyloric region, especially if pedunculated, they tend to prolapse into this opening and through a ball valve action, cause complete obstruction with corresponding physical disturbances—namely, gastric distention, food retention, gastrosuccorrhea and peristaltic rigidity.

The one sure means of diagnosis is, of course, the accidental finding and examination of a tumor fragment in the vomitus, stomach washing or feces. Next to this, and short of autoptic exploration, our dependence must be placed upon röntgenology. The first publication on the radiological diagnosis of these growths without prior findings of tumor fragments in the stomach contents, was mine in 1916 (8). While experience is not yet sufficiently extensive to enable the formulation of rules for the differential diagnosis of all types, the following may be said to be the röntgenological characteristics of the pedunculated varieties: 1. In benign tumor, the outlines of the defect are sharp and not ragged or irregular as in cancer. 2. The greater and lesser curvatures are not implicated in the defect, and there is no break in the peristaltic wave—a pathognomic sign first pointed out by Holmes (9). 3. With change in posture, the plates show a change in the size and position of the filling defect, indicating a shifting of the tumor. 4. In cancer of the stomach the shadow is uniformly opaque, whereas in the softer types of benign polypi or angiomata the shadow is translucent, presents a mottled appearance and sometimes even permits a view of the barium filled coils of small intestines that lie behind the tumor mass.

Where x ray findings indicate a large tumor, while the associated clinical phenomena are not as severe as those which usually accompany advanced cancer, the alternate possibility of benignancy should receive immediate consideration. When cancer shows a large filling defect, the disease has already so far advanced that the other characteristic clinical signs are unmis-

takable. Where, however, these characteristic signs are absent, a large shadow defect points to benignancy and an exploratory operation should be advised immediately.

Surely the subject is of sufficient importance to engage the more earnest attention of the profession, so that we may not continue to condemn as "inoperable cancers," patients who can be saved by a timely exploratory gastrotomy and the removal of a benign tumor.

Tuberculosis.—Under this heading, functional dyspeptic disturbances, so common in advanced pulmonary tuberculosis, are not considered, but only actual pathological lesions that occur in the stomach through primary or secondary invasion of that organ by the tubercle bacillus. The ulcerative and the miliary tubercle types do not simulate cancer; hence, they are left out of the present discussion. In all types the pyloric region is mainly affected. The hypertrophic and the hyperplastic forms, when affecting the epithelium, often give rise to a widespread adenomatous proliferation, and, when involving the submucosa or the deeper layers of the gastric wall, result in a diffuse hard inflammatory infiltration and thickening, or in a circumscribed tumor mass that frequently causes pyloric stenosis.

In themselves these changes sufficiently simulate cancer, but the resemblance is enhanced through associated multiple lymph gland enlargements and perigastric adhesions to surrounding structures. These adhesions are at times very extensive, and bind the stomach and adjacent structures into large irregular and more or less dense and inseparable tumor mass, that has often been mistaken for cancers even by careful observers. Alexander (10), Albu (11), Van Wart (12), Severin (13), and others have reported operations on supposedly gastric cancers that proved to be tuberculosis. This is not surprising when we realize that there are no pathognomonic symptoms of gastric tuberculosis and that it has many manifestations in common with gastric cancer. In both affections the clinical history is short and there is marked emaciation, vomiting, lack of appetite, progressive weakness and increased dyspepsia after solid food. The gastric contents in these tuberculous tumors very frequently show absence of hydrochloric acid and the presence of lactic acid, as well as of occult blood, coffee ground sediment and food stagnation. The röntgen rays may show shadow defects like those of cancer.

When symptoms of gastric cancer are present in a patient with active tuberculosis of some other part of the body, the probability that the gastric lesion is tuberculous rather than otherwise should always be borne in mind. A diagnostic point is that the period of predilection for cancer is after the age of forty, while that for gastric tuberculosis is before thirty. Probably, too, the Wolff-Junghans test is negative, though reports on this fact are lacking in the literature.

Syphilis.—Tertiary syphilis can produce gastric lesions closely simulating cancer. These include small and large multiple gummas, infiltrating sclerosis and ulcerations, with resulting tumor formations, fibrous hyperplasia, often very extensive, of the various layers of the stomach, gastritis or even atrophy of the mucous membrane, varying degrees of induration and thickening of the walls, hourglass and other mutilating deformities, as well as more or less extensive perigastric adhesions. Pathologically, these changes very much resemble those of tuberculosis, just considered. They, too, favor the pyloric region. Hemmeter (14), Muehlmann (15), and Suermondt (16) have reported luetic stomachs so thickened and shrunken that the capacity of each was very considerably reduced. Such stomachs, as Sailer (17) pointed out, cannot be distinguished grossly from linitis plastica and some types of scirrhous cancers.

The differentiation from cancer is most important because of the prognosis and the therapeutic outcome. It is very difficult and in the advanced cases may be impossible short of histological examination. In both conditions there may be gastric pain, vomiting, nausea, hematemesis, melena, pallor and marked loss in weight, gastric tenderness, the presence of a tumor, pyloric obstruction, pronounced subacidity or achylia and very similar x ray findings. The pain in the uncomplicated gummatous ulcerlike type, as in benign ulcer, comes on from one to three hours after meals, while in the more complicated cancerlike forms it is constant as in that disease, and is not relieved or only slightly so by food ingestion, and oftener made worse thereby. Nausea is relatively uncommon, as are also hematemesis and melena, although severe and even fatal hemorrhages have been reported. Loss in weight appears to be a definite accompaniment of the cancerlike forms of gastric syphilis, fully equalling that of cancer. An important point, however, is that the anemia and weakness are usually relatively mild and not in keeping with the emaciation. Subacidity, or achylia, is almost always found in advanced organic gastric syphilis. This fact has been emphasized by Hausmann (18), Neugebauer (19), Eusterman (20), Clark (21), and many others. The Wolff-Junghans test is inconstant, according to Smithies (22), who would reserve it rather as a confirmatory finding in cancer. He has found a low formol index fairly constant in gastric syphilis and suggests it as "promising to furnish an important point of differentiation from malignant lesions" in which he finds it to be much higher.

As may be expected from the pathological changes, the röntgenological findings in advanced luetic conditions are very suggestive of gastric cancer. They include filling defects, infiltrations, hourglass and other mutilating deformities, multiple strictures, shrinkage of part or the entire stomach, adhesions, secondary esophageal dilatation, etc. These findings have been very fully described by Le Wald (23), Mills (24), Eusterman (20), and others. All agree that the röntgenological evidence, though most suggestive, especially in experienced hands, is insufficient *per se* for differentiation from malignancy, and must be interpreted in connection with all the other clinical data.

The diagnosis, therefore, must depend chiefly upon a history of a specific infection, the evidence of luetic stigmata and especially upon the serological tests. The history, as is well known, often falls short of desired facts. Other luetic stigmata, if present, are most suggestive. A clinical diagnosis, whenever made, has been based upon a positive serological test or the result of specific therapy. The latter method, however, is not conclusive evidence unless it results

in a cure or a decided and lasting improvement of all but the irremediable sclerosed conditions. The serological test, especially a consistently positive reaction, is after all our greatest dependence for a diagnosis of gastric syphilis.[1] It must be remembered, however, that in syphilitics nonspecific gastric lesions may and frequently are developed. Cases of coexisting lues and cancer have also been reported in medical literature (25). Finally, too, a negative serological reaction does not necessarily exclude possible gastric syphilis.

CONDITIONS IN WHICH A TUMOR MASS IS NOT PRESENT

Chronic gastritis.—The fact that a catarrhal state always accompanies cancer, may at first give rise to some speculation when one encounters a gastritis in a person within the cancer age. In both diseases test meal examination reveals excessive mucus and diminished gastric acidity. Here the present histories, and the previous histories more so, are of prime importance. There is the same lack of appetite, especially the aversion to meat, and similar dyspeptic complaints, such as gas pressure, bloating, belching, nausea, etc. In cancer, as a rule, these disturbances are constant and of recent origin, while in gastritis they are of long duration and directly associated with food ingestion. In cancer, too, there is a more pronounced suggestion of serious constitutional disease. The point tenderness in cancer is local, while in benign gastritis the tenderness, if present at all, extends more or less over the entire gastric area. During the early stages of the hemorrhagic form of gastritis, differentiation from cancer is difficult and may be impossible. Later on it is easier, owing to the development in cancer of a tumor or a local resistance with tenderness, of a positive Wolff-Junghans reaction, of lactic acid, stagnation of stomach contents, etc. The x ray findings are, of course, essentially different in the two diseases and should very soon clear up the differential diagnosis.

Benign (functional) achylia gastrica.—This is differentiated from cancer by the longer history, the better appetite and physical well being and the absence of real pain. In benign achylia the patients with good stomach motility are generally well nourished and even plump. There is usually a tendency to diarrhea and other intestinal upsets. In cancer, vomiting is common; in benign achylia, rare. In cancer the tongue is coated, the breath foul and the gums usually in poor condition, while in benign achylia, the mouth conditions are normal. The stomach contents and feces in benign achylia lack the presence of blood, so characteristic of cancer; lactic acid, too, is absent and the Wolff-Junghans reaction negative. Tumor formation, resistance or decided point tenderness are not associated with simple benign achylia. As a rule, in cancer the x ray findings are positive and generally diagnostic, while they are negative in benign achylia gastrica.

Pernicious anemia.—This, strictly speaking, is not a stomach affection, but the gastric changes are so constant as to form an essential part of the disease and to be regarded by many as standing in etiological relationship. Clinically, pernicious anemia very closely simulates gastric cancer, and in the absence of a palpable tumor, particularly in the early stages of cancer, a differentiation is at times most difficult or even impossible. With a positive blood picture of pernicious anemia on the one hand, or a typical röntgenogram of cancer on the other, the diagnosis is at once cleared up. But frequently x rays and blood findings are atypical, and the problem becomes most puzzling. I have enountered cases where a correct diagnosis was possible only through autopsy or exploratory laparotomy. For while the anemia of cancer, even when profound, is always secondary, definite criteria of a primary type of anemia are at times lacking in the pernicious variety. A point of great value is that in cancer, the patients, with very few exceptions, markedly and progressively emaciate, while in pernicious anemia, even in exitus, the patients though very pale, usually remain relatively stout.

In pernicious anemia, too, a complete achylia of the benign type is almost invariably present, and what has been mentioned under benign achylia in regard to the differentiation of the stomach contents, applies equally well here. The presence of any diagnostic tumor fragments in the vomitus or the stomach contents at once clears up the diagnosis, but unfortunately, this is a very rare finding in relatively early cancer cases.

SUMMARY

In the *average* case within this subacid gastric group a detailed study, utilizing the elaborated diagnostic criteria outlined above pertaining to the history, the physical and laboratory findings, combined wherever possible with a complete röntgenological examination, will readily suffice to establish a definite diagnosis for or against the presence of a gastric cancer. Occasionally an extremely atypical case that baffles the skill of the most experienced and expert diagnostician will be encountered, and a correct diagnosis prove impossible short of surgical and perhaps, too, of histological investigation. Between these extreme types one not infrequently meets with cases that puzzle the average investigator. Here clarification of the situation can be arrived at only through most painstaking attention to every diagnostic detail, coupled with intelligent application of past experience, bearing well in mind all conditions that may possibly fit into the clinical picture.

CONCLUSIONS

1. Unless the presence of a cancer in the stomach has been positively established, the possibility of a noncancerous process should receive equal consideration.

2. Exploratory laparotomy is particularly urged whenever a careful study of a suspicious subacid case presents some feature which does not fit into the classical picture of gastric cancer.

3. This is particularly true in very early cases, for whether the process be cancerous or not, other things being equal, the patient's chance for recovery in surgical gastric affections is in direct proportion to the timeliness of the operative procedure.

[1] In March, 1923, at a meeting of the Bronx County Medical Society, Dr. L. T. LeWald gave a lantern slide exhibition of Spirochæta pallida found postmortem in the stomach wall of a patient who had been refused surgical intervention because the case was considered an "inoperable cancer." According to Dr. LeWald, this was the first histological demonstration of the kind.

A complete bibliography will be included in the author's reprints.

Instruments, Apparatus, and Clinical Notes

Clinical Applications of the Duodenogram*

JACOB BUCKSTEIN, M.D.
New York

Radiographic study of the contour of the entire duodenum beyond the first portion, has been difficult, because of the failure to visualize it in an isolated and unobstructed manner. Ordinarily two main difficulties are encountered, when the ingested barium suspension is employed. In the first place, the flow of barium from the stomach into the duodenum is intermittent, because of the controlling function of the pyloric sphincter. In addition the barium as it reaches the duodenum is rapidly hurried on its way. Thus, a complete homogeneous filling of the entire duodenum is rarely ever obtained. In the second place the barium filled stomach, by overlapping, frequently obscures part of the transverse duodenum and duodenojejunal junction. I have devised a simple means for overcoming the two difficulties mentioned. An ordinary rubber duodenal or intestinal tube is employed. The distal ten inches of tubing is severed and is perforated with numerous small holes, each about as large as the lumen. This piece of tubing is then joined to the larger piece of rubber, by means of a small metal connection. The tube is swallowed by the patient and the end allowed to reach the duodenum after the ordinary manner of duodenal intubation. The purpose of the metal connecting piece is to ascertain whether the beginning

FIG. 1.—Duodenogram obtained in a patient of hyposthenic habitus.

FIG. 2.—Duodenogram obtained in a patient of sthenic habitus.

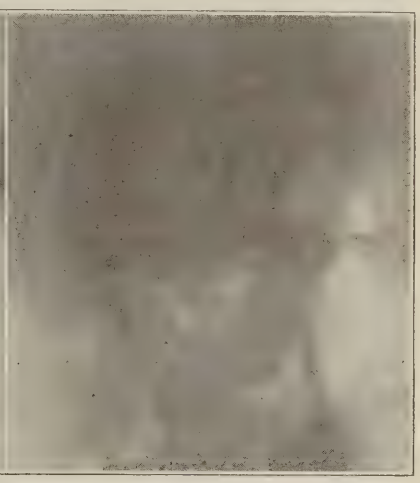

FIG. 3.—Duodenogram obtained in a patient of hypersthenic habitus.

*From the Radiography Department, Bellevue Hospital, Dr. I. Seth Hirsch, director.

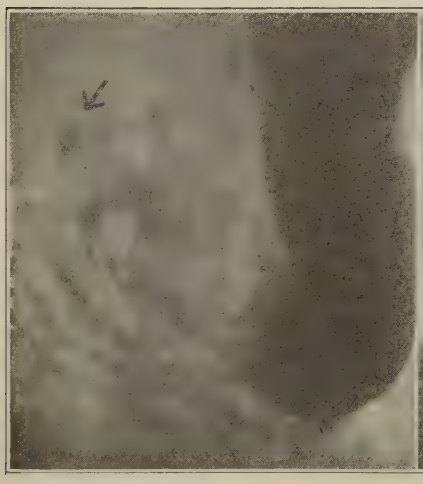

FIG. 4.—Arrow points to saccular dilatation as noted following the ordinary ingested barium meal. By this method the duodenojejunal junction is frequently obscured by overlapping of the barium filled stomach.

FIG. 5.—Same case as Fig. 4. A specially constructed intestinal tube is here shown in situ. The metal connecting piece had not yet been devised. This joins a small perforated piece of tubing to the larger piece.

FIG. 6.—Same case as Fig. 4. Arrow points to saccular dilatation as noted by means of the duodenogram. Note how much more clearly its anatomical relations are defined as compared to Fig. 4.

Fig. 7.—Arrow points to a duodenojejunal diverticulum as noted following the ordinary injested barium meal. There is an associated duodenal deformity.

The duodenogram is a clear radiographic means of differentiation between a duodenal diverticulum and a perforated gastric ulcer.

Fig. 8.—Arrow points to a duodenojejunal diverticulum (same case as Fig. 7) as noted by means of the duodenogram. Note how clearly its exact anatomical relations are defined. Also, how exactly it is shown to be a diverticulum, and not a possible perforating ulcer of the stomach. (Note the associated duodenal deformity.)

Fig. 9.—Duodenogram obtained in a patient showing puddling at the junction of the second and third portions of the duodenum, with reverse peristalsis. The arrow points to a marked diminution in the lumen of the midportion of the transverse duodenum, as the probable cause. This condition is apparently due to spasm in that region.

of the perforations coincides with the beginning of the duodenum. If the tube has not passed sufficiently far, or has passed too far into the duodenum, proper adjustment may be made under fluoroscopic control until the metal connection is properly placed. In this manner the perforated distal portion is made to correspond to the entire course of the duodenal curve, including the duodenojejunal junction. About sixty c. c. of a suspension of barium to which a small amount of acacia has been added is then injected through the proximal end. This mixture on escaping through the distal perforations fills the entire duodenal curve in a complete and homogenous manner. Radiographic films are taken immediately and preferably in the standing position to avoid spine pressure.

I have been able to demonstrate the following applications of the method. I have obtained duodenograms in patients of varying habitus. While there are variations in the position of the duodenal curve associated with the normal variations in the position of the stomach, the size of the duodenal curve bears no constant relation to the habitus. (Fig. 1, 2, 3.)

This is of practical clinical significance in that marked enlargements of the duodenal curve may, regardless of the habitus of the patient, be suggestive of enlargements of the head of the pancreas. The value of the procedure in this connection has been referred to in a former communication (1). The duodenogram is of value in the clear demonstration of sacculations springing from any portion of the duodenum. (Fig. 4, 5, 6, 7, 8.) I wish to emphasize particularly the usefulness of the method in the case of duodenojejunal diverticula. By the ordinary ingested meal method the duodenojejunal junction is frequently entirely obscured by overlapping of the barium filled stomach. The duodenogram brings the duodenojejunal junction into clear relief, and demonstrates the diverticulum as it springs directly from this region. It is especially significant, as a clear radiographic means of differentiation, in a doubtful case between a diverticulum and a possible perforated ulcer of the stomach. (Compare Figs. 7 and 8 from that point of view.)

For an unobstructed view of the entire transverse duodenum the duodenogram is of value. A not infrequent finding in studying duodenal motility is that of puddling of barium at the junction of the second and third portions of the duodenum, with reverse peristalsis extending from this region back towards the pylorus. In its extreme manifestation it gives rise to a writhing motion. Figure 9 represents the duodenogram obtained in a patient in whom the duodenum behaved in this manner.

In the midportion of the transverse duodenum beyond the area of puddling the arrows indicate a zone of marked constriction. An exploratory laparotomy in this patient disclosed the presence of gallbladder disease, but no evidence of organic interference with the transverse duodenum. In my opinion the constriction indicated in the duodenogram is functional in nature, due to spasm, and is the cause of the puddling and reverse peristalsis in the proximal portion of the duodenum.

SUMMARY

1. A simple method is described for obtaining an unobstructed view of a homogenously filled entire duodenal curve. This I have called a duodenogram.

2. There is no variation in the size of the duodenal curve, as compared to variations in body habitus.

3. Enlargements of the duodenal curve suggest the presence of tumors of the head of the pancreas.

4. The duodenogram is of value in the clear demonstration of duodenal diverticula.

5. The method may be employed in exact differentiation between a duodenojejunal diverticulum and a suspected perforated ulcer of the stomach.

6. In studying the phenomena of duodenal motility light may be thrown upon the subject by means of the duodenogram.

A NEW RAPID PANCHROMATIC BLOOD STAIN*

FREDERIC PROESCHER, M.D.,
AND ALBERT S. ARKUSH, A.B.
Agnew, Calif.

The authors have recently submitted an article for publication to the *Journal of Laboratory and Clinical Medicine* in which they describe a new rapid blood stain. The preparation of the stain and procedure follow.

Mix equal parts (sixty mgm each) of methylene blue, thiazin red (methylene azur), and eosin with twenty-five c.c. distilled water and add fifty c.c. acetone. To stain the smear, cover it with a few drops of the staining solution, pour off the excess stain, and allow the adhering solution to remain at least thirty seconds. Wash with tap water.

Recent work has shown us that a simple modification of this stain is possible, wherein the picture obtained may be considerably improved for purposes of cell study. Moreover, large variation in staining effect is possible by altering the procedure. To obtain this new stain, add sixty mgm azur II eosin to that described above.

This solution may be used as a rapid stain, as before modification, or allowed to stand from five to twenty minutes without pouring the stain from the smear. The variation in effect is largely due to the rate of evaporation of the acetone.

The result obtained with the modified stain is practically the same as with a combined May-Grünwald-Giemsa stain. The granules of the neutrophiles, eosinophiles, and basophiles are more distinctly stained than with any other method. This is especially noticed in smears from leukemia blood where premature granules are excellently brought out. In addition to the more obvious advantages of this method it may also be noted that danger from overstaining has been removed.

HOW THE DUODENAL TUBE MAY BE PASSED IN HIGHSTRUNG PATIENTS WITHOUT CAUSING EXCITEMENT

CHARLES EVERETT HAINES, M.D.
New Rochelle, N. Y.

During the past few years there has been considerable discussion with regard to the use of the duodenal tube in gastrointestinal surgery. Direct alimentation has thus become possible and the patient is no longer starved for several days postoperatively, as is often the case when the tube is not used. Usually, the tube is passed before the anesthetic is begun.

However, the fear of an operation is quite as much as a patient ought to be expected to stand without the fuss and excitement attendant upon taking a duodenal tube, especially for the first time.

Thus it may frequently seem desirable to pass the duodenal tube after the patient is under the anesthetic. But as the tube is made of soft rubber, it is not possible to pass it down the esophagus like the stiffer stomach tube without cooperation on the part of the patient. If, however, the duodenal tube could be made temporarily stiff like a stomach tube there would be no difficulty in passing it after the patient is narcotized, thus securing postoperative alimentation without what sometimes amounts to torture.

I have thus stiffened a duodenal tube and successfully passed it on a comatose patient.

A fine piano wire a little longer than the duodenal tube was bent at one end to form a small eye—the eye being large enough to prevent the wire from slipping through the holes in the bucket and yet small enough to be withdrawn through the lumen of the tube. The tube threaded with the wire and thus stiffened was then passed through the mouth of the patient and into the stomach. With a little manipulation of the wire it was withdrawn and the tube left *in situ*.

In operative cases it is suggested that the bucket be manually put into the duodenum by the surgeon while the abdomen is open.

181 NORTH AVENUE.

A Modified Clavicular Cross.—B. B. Landry (*Surgery, Gynecology and Obstetrics,* April, 1925) recommends a convenient modification made in the form of an adjustable cross which is applicable to the treatment of clavicular fractures by the socalled crucifixion method. It can be readily adjusted to patients of all sizes. It consists of five pieces of seasoned maple, the cross piece and spinal piece being joined at right angles by five small screws. For convenience in transportation these may be removed and the parts placed in opposition. In the longitudinal axis of each arm of the cross there is a slotted portion which allows this piece to be moved along a screw bar. This piece is held in the position desired by tightening the screw which is fixed to the cross piece. The screw for adjusting the spinal piece is fastened to the movable part. By means of this screw the splint can be adjusted to the shoulders and the sacral promontory. A small square block is held at the end of each movable portion by two screws which also hold the webbing firmly. The padding and the rubber tubing which is placed over the webbing to prevent chafing differ in no way from those of the unadjustable clavicular cross.

Bifurcation in Irreducible Dislocations of the Hip.—R. S. Reich (*Journal of Bone and Joint Surgery,* July, 1925) holds that the bifurcation operation is indicated in all types of irreducible dislocations of hip joint, in patients upon whom bloodless reduction has been unsuccessful, or who have passed the favorable age limit. Any procedure designed to reconstruct the hip joint should have for its primary object the restoration of the anteroposterior equilibrium of the body in order to overcome the lordosis. The operation has been successfully employed in cases of ununited fracture of the neck of the femur. Although the successful replacement of the head into the acetabulum is the ideal procedure, nevertheless, the bifurcation operation achieves equally good results by a procedure which is extraarticular, is attended with practically no shock, requires a very short time for its performance, overcomes the lordosis, and produces a movable hip joint. There may be a slight amount of increased shortening, which is negligible and easily overcome.

Editorial Articles

REGULATING THE WEATHER

Each of us can be his own weatherman indoors, that is, if he is in a position to have his own way. In his own office and in his own living room he can keep the mercury from dropping to the bottom or, what is more likely in most offices, from climbing to the top of the thermometer. He can also regulate, so far as is needful, the amount of moisture and the degree of air motion to his needs.

As a matter of public health, as well as of public and private wealth, we need somehow to bring about a similar regulation of the weather in public places—in schools, theatres, churches, and in stores. In schools we are making considerable progress in this direction and the child is not nearly so often stifled in his own suppressed heat as formerly. Not infrequently, however, one finds a temperature of 80°, or even higher, in supposedly well regulated school systems. Theatres are much better weathered than formerly, but in stores and office buildings a tropical climate prevails to an almost universal extent and the menace to public health, especially in large stores, is very great indeed, while the extravagance in the consumption of coal is unpardonable.

People who shop (and this means well nigh the whole population) enter the store, in winter, clad for out of door weather. They encounter the heat of the Sahara at noontide, and on leaving the place are in prime condition to be chilled and to come down with colds, pneumonia, and the like diseases for which they are thus prepared. We have no statistics, but it is safe to say that half the colds—perhaps a larger per cent.—are contracted after passing from a room that is too hot (whether at home or in public place) to the out of doors.

Our departments of public health are very particular to inspect restaurants, barber shops, and the like, in search of parasites and their carriers, which, in a very few instances, cause some skin diseases, or possibly typhoid. No attention is paid by these departments to control, either by regulation and inspection or by attempts to educate the public, the temperature at which, for safety, stores and other public places might be kept. And yet some forty per cent. of the illnesses which occur are from respiratory affections, and, moreover, pneumonia stands very high in frequency among the causes of death.

The saving in fuel which would result from such a regulation of the weather as might be brought about would more than pay for the work of visitation of these public incubators, and for a publication, from time to time, of a list of those stores where it is safest to shop, and there is every reason why the management of a store should wish to comply with such a regulation or request. Just what the best temperature for shopping should be, we do not know, but certainly seventy degrees should be a maximum, and doubtless five or even ten degrees colder might be better. The responsibility for the temperature might well be made to devolve upon the shoulders of the floorwalker.

CHANGED AND CHANGING PRACTICE OF MEDICINE

The practice of medicine is changing in character everywhere, but more so and more rapidly in this country than in any other. Dr. Thierry de Martel, a professor of surgery in the University of Paris and a visitor to the Clinical Congress of Surgeons of North America, held recently in Philadelphia, said that the group method of examining, diagnosing and treating patients so greatly in vogue here was the main point of difference between medical practice in this country and in France.

Dr. Rudolph Matas, the distinguished surgeon of New Orleans, and president of the College of Surgeons of America, made the change in the practice of medicine the chief theme of his eloquent presidential address, while Lord Dawson of Penn, who gave the fellowship address on the same evening, took up the same subject. Dr. Matas pointed out that specialists now rule medicine and he thought that the public were convinced that the hospital supplied the most adequate treatment of human ills.

He, moreover, believed that not only would the hospital in the future treat and care for almost all human sickness, but that surgery would assume the predominant rôle in treatment. He thought that the "family doctor" would be transformed into a new kind of creature, or rather that his part in the scheme of medical affairs would be wholly altered. In place of being the family attendant upon whose shoulders fall the medical care of the household, his work would be somewhat of the nature of the public health official of today and an intermediary between the patient and the specialist.

Dr. Matas emphasized the fact that it must be borne in mind that we were living in a transition period in the history of medical organization which had no parallel in past epochs. The system of organization under which the medical profession of this country had lived in fair comfort up to the last quarter of the century was rapidly disintegrating

and yielding to the pressure of unforeseen conditions which were creating new methods of medical service. The old general practitioner who, up to the present, had represented the unit of service in this country, was no longer able to carry singlehanded the great load of responsibility that was being heaped upon him by the new and rapidly accumulating discoveries of modern medical science and its collateral branches. No one brain could carry all the knowledge that was required to discharge adequately the duties of a general medical practice that amply sufficed thirty years ago. Nowadays the work once performed by one man required three, five or more to do it well.

Meanwhile, the general public, at least the majority who have become aware that the best and most economical medical and surgical services are procurable in the hospitals, are drifting from the family practitioner to hospitals, specialists, or the group clinics, but to the hospitals especially. Dr. Matas has a vision of a new type of doctor who will find his chief occupation as a sanitary adviser and public health official.

Lord Dawson urged a hospital for every community, no matter how rural, but the family doctor should remain the foundation of medical service, although his outlook, functions and training required modification to meet changing needs.

A little book has been published recently by G. P. Putnams Sons, Ltd., written by that great authority on public health matters in England, Sir Arthur Newsholme, in which the changing character of medical practice in that country is discussed. The attempt is made in the book to demonstrate that the general welfare of the community is more dependent on the prompt and efficient treatment of disease, on its prevention, and on the enhancement of the general standard of public health and personal hygiene than on any other condition.

In the changing character of medical practice the old type of general practitioner will pass and probably he will find his scope of usefulness, chiefly in the field of preventive medicine. But it will not be altogether in public health. In civilized countries sanitary measures properly enforced have abolished great epidemics, or robbed them of most of their menace. The battle now is against the chronic diseases, which arise largely through neglect of adequate care in childhood and which lead to the most mortal and disabling diseases. The trend of preventive medicine is towards infant welfare and personal and domestic hygiene generally. It may be predicted that the province of the medical man of the future will be to a large extent that of an educator, a teacher of healthy ways in which to rear children, and of personal and domestic hygiene.

LIGHT

Medical people and hygienists must always have some curative or preventive which they laud without sense or reason. Of late it was vitamines which were given undue recognizance, and at present light is in the limelight. Always it is some condition the importance of which was known to our lower (?) animal friends for ages, and neglected by man only, which is now hailed as a lost and only factor for health.

Everybody appreciates sunlight, and we are all sun worshipers, at least on dark days. That it has specific effects on metabolism may be a new item of exact knowledge, but it is unnecessary to anyone who lives a natural life and with a dietary such as any but experimental animals are supposed to have.

While it is well to have ample exposure to light, there is more danger in overexposure than in underexposure, and we are likely to have a fine crop of sunburn, if no worse results obtain from our present light science. It has long been a fad of fashion rather than of hygiene to become tanned in summer, and incidentally this has been pronounced by lay teachers as invaluable to health. As a matter of fact, tanning is only a means of protection of the body against sunburn, which is far from helpful, and, save as a protector, has no relation to health. The Eskimo child has the finest teeth in the world, despite six months of sunlessness. The negro is no healthier than the Caucasian nor the Italian than the Norwegian, the Hottentot than the Pittsburgher or Londoner.

So far as the practice of medicine is concerned, we may expect the lighting machine to supplant the high frequency machine, though it is less spectacular. History would only be repeating herself with new contrivances. A half century ago it was light coming through blue glass that did the business, and in many a house will be found a window supplied with panes transmitting only this color. Before this window sat one or more rheumatic members of the family and took the cure, though they were not always cured.

Light is essential for plants, but it is not proved that it is essential for properly fed animals. At any rate, many animals thrive from infancy in the dark, and the miner, who spends most of his day below ground, is not unhealthy. Even if it is a necessary factor in human growth, we have no business doing harm by letting it overshadow in importance the essentials, for, as Mark Twain said of the premature report of his demise, some of the popular preaching about the results of exposure to light are likely to be "grossly exaggerated" and to do as much harm as good. Let there be light, but not too much of it.

The last sentence has always been the hygiene followed by the animals. Artificial lighting of monkey cages in the London Zoo has recently been tried and, of course, the denizens seek the light and bask in it, but, if it were the direct light from a tropical sun, they would be the first to seek shelter in the cool and shady depths of the forest.

HOUSING AND HEALTH

So far as the prevention of disease and conditions of ill health is concerned nothing is of so great importance as the effects of environment, and of good housing in particular. In the prevention of tuberculosis well ventilated, clean houses and the presence of sunshine are essential. Rickets is another condition which can only be prevented, or successfully treated, by sunshine, fresh air and exercise.

However, in the case of rickets the pendulum has now swung too far in the direction of these preventive and curative measures. It is stoutly affirmed by some authorities that rickets is a disease due solely to the absence of fresh air and sunlight and to the lack of exercise in the open. Not long ago it was asserted with equal insistence that it was a diabetic disease and was labeled by many a dietetic deficiency disease. While the researches of Paton, Finlay, of Glasgow, Hess and other American investigators have shown that sunlight, good air, exercise and healthy surroundings have much to do with the absence of rickets, it yet seems a palpable exaggeration to state that these are the sole causes and that diet is a negligible factor.

Diet plays a part in its causation. But it is absolutely true that the conditions prevailing in the poor districts of large cities, and especially in industrial cities, provide hotbeds for the development of rickets, tuberculosis and many other diseases. In fact, the provision of an adequate supply of good houses with plenty of open spaces is necessary for the prevention of disease, and it is obvious that until slum areas are cleared away disease will continue on a wide scale.

Rickets is largely responsible for defects, such as the altered shape of the chest, defective growth of the teeth, in the formation of the palate which is high and arched, in the thickening which occurs over the forehead and over the back of the skull, and in such deformities as flat foot, lateral curvature, and knock knee.

To the conditions of life in the slums, including, be it said, inadequate and improper food, a heavy toll in deaths from infectious diseases is owing. Of these, measles, whooping cough and bronchitis are among the most prominent. Perhaps the majority of the severe cases of difficult labor is due to the fact that the mother has at an early date suffered from rickets. The orthopedic departments of our hospitals are largely supplied by deformities arising from rickets and tuberculosis.

Unhealthy housing and environment cause much ill health and are responsible to a large extent for the product of the poorer parts of the big towns of today, the ineffective type of adult, deficient alike in physical stamina and in nervous energy and stability. It is not only better houses that are needed, but the supply of healthy environment to the young child, so that it may have its fair share of sunshine and fresh air and the opportunity for exercise in the open. Good housing and healthy surroundings with a sufficiency of unsophisticated food would create a revolution in the type of the human product of cities and would be the longest step ever made in the direction of the prevention of disease.

CONGRESS FOR DIGESTIVE DISEASES AND METABOLISM

A meeting of the Association for the Diseases of Digestion and Metabolism was held in Vienna from September 30th to October 3rd, inclusive, under the chairmanship of Professor L. Kuttner, of Berlin. Over six hundred members from all parts of the world were present. The German and Austrian physicians and surgeons formed the bulk of the association. There were present, besides, a number of well known physicians from Holland, Sweden, Norway, Denmark, Finland, Russia, Poland, Latvia, Hungary, Czechoslovakia, Italy, Spain, the United States, Canada, and Brazil. Excellent papers on metabolism and digestive diseases were read and discussed. A few of these appear in this issue of the JOURNAL in a symposium on gastroenterology.

The executive committee of this association decided to elect permanent members and to hold meetings yearly either at Berlin or Vienna, alternately.

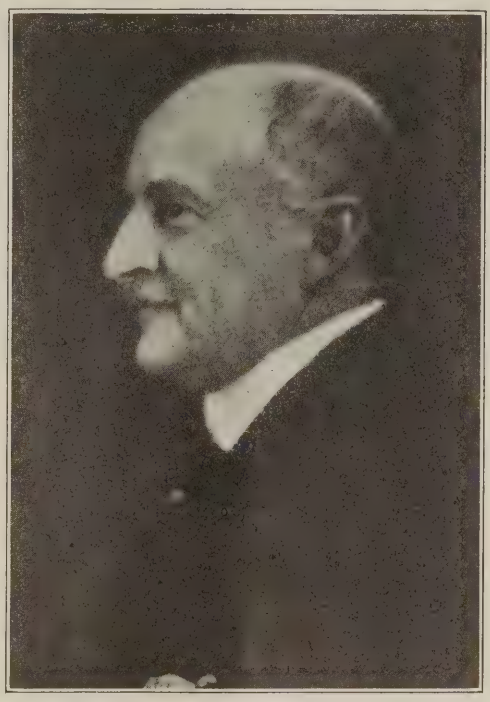
Vienna proved to be very hospitable. There was a special performance of *Der Rosenkavalier* given in the Opera House for members of the congress. An excellent banquet was given by the Vienna physicians at the Imperial Hotel for a selected group of noted members of the congress and readers of papers. There were also numerous social entertainments for the visiting ladies. An excursion was arranged to the Semmering, where the guests could spent a few days in this well known mountain resort. Altogether the congress was a great success scientifically as well as socially, and everybody who had the good fortune to be there felt the desire to come again. The next congress will take place in 1926 in Berlin, under the presidency of von Bergmann of Frankfurt.

Obituary.

NATHAN EDWIN BRILL, M.D.

B. SACHS, M.D.
New York

In the death of Dr. Nathan E. Brill, the medical profession and the community have suffered a real and serious loss. To a rare degree he combined the finer qualities of a learned physician with those of a man of culture and refinement. In his professional relations to his colleagues and to his patients he was the man of splendid acquirements, skilful in practice, upright and even aggressive in defense of his views, eager to advance medical science, justly proud of what he had achieved. He realized his obligations to the community in which he was born and bred, giving the best that was in him to every forward civic movement, and proving by his diverse activities that the medical man has unusual opportunities, if he will only avail himself of them, to be of great service to his fellow man.



NATHAN EDWIN BRILL, M.D.

Dr. Brill was born in this city January 13, 1860; he was trained in the public schools and was graduated from the College of the City of New York, taking his degree of A.B. in 1877, and of A.M. in 1883. He studied medicine at the New York University Medical College; he received his medical degree in 1880. From 1879 to 1881 he was an intern at Bellevue Hospital. While devoting himself chiefly to the study and practice of general medicine, he took especial interest in neurology and in the early eighties, stimulated by close association with Edward A. Spitzka, did good work in the comparative anatomy of the nervous system, contributing to medical literature a very valuable monograph on congenital defects of the nervous system. Brill maintained his interest in neurological science throughout his life and was a familiar and welcome figure at many neurological meetings.

In 1893 Brill was appointed attending physician to Mount Sinai Hospital. During a period of over thirty years he was active and energetic as investigator and clinical teacher. Although fully alive to the progress of medical science, and aware of the importance of the biological and chemical laboratories in the study of disease, he developed keen clinical insight and belonged to that small and ever diminishing group of clinicians who believe that the diagnosis can and should be made at the bedside, and that observation of the patient is as important as are many of the laboratory tests.

His description in 1910 of the endemic form of typhus fever (now known as Brill's disease) revealed his skill as a careful medical observer. He maintained his interest in all forms of acute infectious diseases. Leucemia and all forms of blood disease exercised a special fascination over him. He was a true master in this domain. His articles on the Gaucher type of splenomegaly, his discussion of the diseases of the blood forming organs, his study of the value of splenectomy in thrombocytopenic (essential) purpura, showed his unusual grasp of an important series of newly recognized forms of disease.

Much more might be said to record his ability as consulting physician, to recall his excellence as guide to the aspiring medical youth. His services as clinical professor of medicine at the College of Physicians and Surgeons, his active participation in the work of the public health committee of the New York Academy of Medicine, his functions as vice-president and president of the Medical Board of Mount Sinai Hospital, his interest as a member in the affairs of many national and local societies, such as the American Medical Association, the Association of American Physicians, the New York Academy of Medicine, the American Neurological Association, and the Society of Medical Jurisprudence of which he was president from 1892 to 1894—all go to show that his talents were recognized and appreciated. Whatever Brill undertook to do he did well. His heart and soul were always in the task before him.

To his great chagrin, ill health prevented his going overseas; but he did his patriotic best in directing the work of Base Hospital No. 3. He was proud of his rank as major in the United States Army Medical Corps. At all times he was intensely American in his feeling and his judgment. In 1917 the first signs of the fatal illness appeared. Hampered as he was by loss of voice, he "carried on" for several years, displaying an indomitable will and enviable courage. His friend, the Rev. Stephen S. Wise, in paying tribute to his many good qualities, emphasized Brill's stoicism—"the courage of an uncomplaining gentleman, who in the face of adversity and trial and infinitely burdensome difficulties, faces life with that courage without bitterness which the world associates with stoicism." Those who visited him during his cruel illness will bear witness to his astounding patience when life had become a distressing struggle. His friends will think lovingly of Brill, the invalid; but they and all medical men will do better to pay homage to the man as he was in his prime and throughout his long and active career. Kindly, cheerful, forceful, a man of high ideals, a fine physician, and, above all, a fearless defender of truth.

New York's New Medical Centre

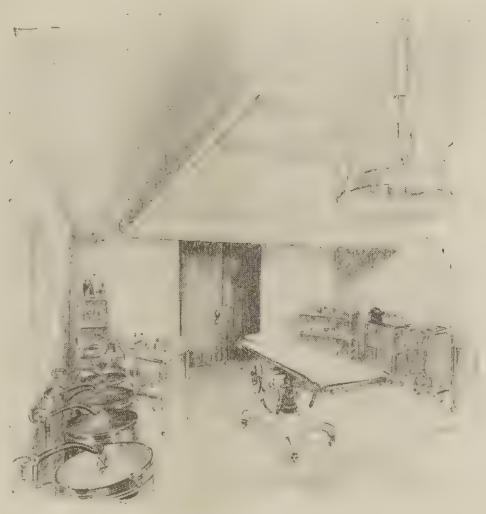
MABEL WEBSTER BROWN, B.S.
New York

"Specialization is the parent of information and of a certain type of skill," said Dr. Nicholas Murray Butler, president of Columbia University, in a recent address, "but it is the foe of knowledge and the mortal enemy of wisdom. Not narrow men, however keen, but broad men sharpened to a point, are the ideal product of a sound system of school and college education." The realization of this fact is back of the revolt of the twentieth century against the overspecialized nineteenth. Since the time of Pasteur men of exceptional ability in the science of medicine have attracted schools of followers, in their turn attended by multitudes of the afflicted. These groups, becoming usually isolated units, played their inevitable and immensely significant part in the growth of medical science by developing and perfecting scientific knowledge along their own particular and individual lines of interest. Then the necessity for coordination became evident, and the best ways to attain it one of the outstanding problems of medical science.

The solution of this problem is the underlying ideal of New York's new Medical Centre, which is being constructed on upper Broadway between 165th and 168th Streets. Its keystone will be a building erected and shared by the Presbyterian Hospital and the College of Physicians and Surgeons of Columbia University. Other institutions, which have agreed to become identified with the Medical Centre, are the New York State Psychiatric Institute and Hospital, now located on Ward's Island, the Neurological Institute, the Babies' Hospital, the Sloane Hospital for Women, the Vanderbilt Clinic, and the Presbyterian Hospital School of Nursing. This list of institutions in itself indicates that the scope of the Medical Centre's work will be threefold—medical care and treatment, the teaching of medical science, and the provision of the best opportunities for scientific research work. There the specialist, who was becoming more and more isolated from specialists in other lines, may find his great contemporaries near at hand; the patient, who has perhaps toured the country for medical advice, will have an opportunity to receive a combined opinion, and to place himself in the hands of a single man if he wishes; the student, the nurse, the research worker, the public health worker, the dentist, the social worker—all may have a single source of knowledge, where theory and practice may be combined. To quote from a recent article of Dr. C. C. Burlingame, executive officer of the joint administrative board of the Medical Centre: "So the public and the patient are demanding an opportunity of once more going to one place where 'all that can be done will be done.' This is the elaboration of the medical centre idea. It is the one place where science can focus upon disease, where knowledge can be imparted to any of the army of health workers, and where the

patient with his disease can find complete care." The success of the medical centre idea has been incontestably demonstrated by such institutions as the Mayo Clinic, Johns Hopkins University and Medical School, the Harvard Medical Centre, and others in St. Louis, Cincinnati, and some of the State universities. In Chicago a similar step has been taken in regard to the Rush Medical School and certain hospitals. Montreal, Berlin and Vienna are among foreign cities where the experiment has been successfully tried out.

The New York Medical Centre had its inception in 1911, when an agreement was effected between Columbia University and the Presbyterian Hospital whereby the latter became a "teaching hospital" for the University's medical school, the College of Physicians and Surgeons. Although these two institutions have been closely allied in this working agreement, they are quite widely separated in distance, and the daily inconvenience and loss of time from such a separation stimulated Dr. Samuel Lambert, at that time Dean of the College of Physicians and Surgeons, to work out a proposed scheme for a medical centre. This was in 1915. After a study of all available sites, an option was obtained on the old American League Baseball Park, and this land was donoted by its owners, Mrs. Stephen V. Harkness and Edward S. Harkness, to the Medical Centre. By 1917 definite plans were being discussed, but the World War prevented the taking of any steps. In 1921 a Joint Administrative Board was formed, and Dr. Burlingame, psychiatrist, who had served as Director of the Medical and Surgical Department of the American Red Cross in France and later as an organizer of industrial medicine, was appointed executive officer. Other members of this joint administrative board are: General William Barclay Parsons, chairman, Mr. Henry W. de Forest, vice-chairman, Mr. Edward S. Harkness, Mr. Dean Sage, Dr. Walter B. James, Mr. John G. Milburn, Mr. John Sherman Hoyt, Mr. Robert Thorne, Mr. Newcomb Carlton, Mr. Jackson E. Reynolds, Mr. W. E. S. Griswold, and Dean William Darrach, ex-officio. The plans for the Medical Centre now under way are based upon a three years' study of hospitals in this country and abroad made by the joint administrative board.



An Operating Room in the New Presbyterian Hospital

The location of the Medical Centre is ideal for its purpose. The twenty acres comprising the site extend from Broadway on the East to Riverside Park on the West. The land at Broadway is high and slopes toward the Hudson. The view of the river and Palisades is magnificent, and there are unlimited fresh air and sunshine. The Interborough Subway and the new subway will have a combined express station at the Centre. The Fifth Avenue buses and several trolley lines pass the grounds. Moreover, the Centre is in the heart of a district with inadequate hospital facilities. In this whole upper portion of Manhattan there are only 789 general hospital beds.

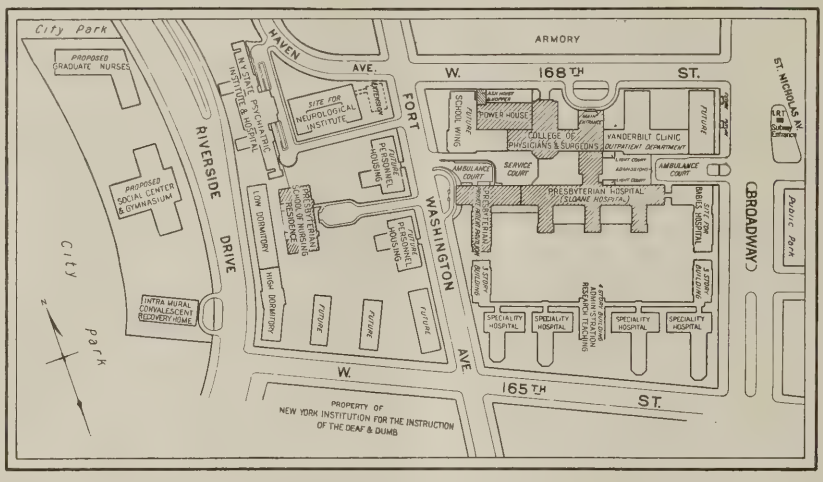
The Centre will represent an investment of approximately $20,000,000. The nucleus of the group of buildings will be a twenty-two story structure which will house the Presbyterian Hospital, the College of Physicians and Surgeons, and the Sloane Hospital for women. Ground was broken for this building on January 31, 1925, and it will be ready for occupancy in the summer of 1927. Connected with this will be a private patient pavilion with 125 rooms. Rapid progress has already been made in building this, for the steel framework is erected and the brick walls are being laid. That part of the central structure which will contain the Presbyterian and Sloane Hospitals will be a series of small hospitals, each floor being practically complete in itself. A ward floor will have sixty-four beds, divided into rooms containing from one to twelve beds, and sun parlors, dressing rooms, treatment rooms where minor operations may be performed, laboratories and kitchens. On the fifteenth floor will be the operating service with eight operating rooms and an amphitheatre seating 135. This will be used also for a meeting place for medical congresses when in session in New York. Six of the operating rooms will have screened mezzanines from which students and visitors may observe operations. Above the operating floor will be a gymnasium and recreation roof with a music room, and two glass enclosed loggias. At each end of the roof will be open courts with tile floors for shuffle board, quoits and other games. The gymnasium will be open to the staff and to patients who need corrective exercises.

The New York State Psychiatric Institute and Hospital will be a twenty story structure with a Riverside Drive entrance on the first floor and an entrance from Haven Avenue on the eleventh floor. This is possible because of a cliff on the property. The building will accommodate two hundred patients between the first and eleventh floors. One floor will be given over to children suffering from mental and nervous disorders, and will be equipped with a school room and play rooms. The ten upper floors will be devoted to laboratories, a museum, a library, class rooms and other facilities for the scientific study and investigation of mental and nervous diseases. The cost of the Institute will be $1,600,000. It was authorized by a special act of the Legislature in 1920. The New York State Hospital Commission selected the Medical Centre site as the one most suitable for carrying out the terms of the Act. Only cases of special interest will be kept at the Institute; others will be sent to one of the fourteen State hospitals in New York State.

The Neurological Institute will erect a modern hospital at the Medical Centre on Haven Avenue next to

the Psychiatric Institute. The site chosen for the Babies' Hospital is on Broadway. Sloane Hospital will have two ward floors in the central building and a floor in the Presbyterian Hospital's private patient pavilion, for observation, with an additional ward and private patient accommodations for gynecological work. The Vanderbilt Clinic will be located in the Presbyterian Hospital's outpatient department.

Work is well under way for the School of Nursing residence, which will overlook Riverside Drive. This building will cost $1,000,000, the money having been raised by nurses and their friends. Only student nurses will be accommodated here, since there will be other provisions for graduate nurses. A tunnel under Fort Washington Avenue will connect the residence with the main group of buildings.



Ground Plan of Medical Centre

Arrangements have recently been completed for the transfer of the J. Kennedy Tod Estate at Sound Beach, Conn., to the Presbyterian Hospital as the site for a convalescent home for Medical Centre patients. The estate consists of a peninsula containing 117 acres and two small islands. It is located on the Sound about thirty-five miles by paved road from the Centre, and is also accessible by water. The grounds include rolling country, fields and meadows, woods, lakes and ocean beach.

The Columbia University College of Dental and Oral Surgery will become identified with the Medical Centre as soon as funds become available for a new building. The Crocker Institute of Cancer Research, and the College of Pharmacy of the City of New York, are expected to join the group eventually. Provision has been made for additional specialty hospitals and schools devoted to the promotion of health and medical science.

The curriculum for students at the Medical Centre will include instruction in all the branches of medical science, dentistry, nursing, oral hygiene, social hygiene, social science, and hospital administration. In care and treatment of the sick, emphasis will always be placed upon a coordination of all forces on the *patient;* he will be the focus of attention—not primarily as an interesting "case," but as an individual man, woman, or child, in need of succor. With conditions such as will prevail at the Medical Centre, it will be the practical thing, in most cases, for the specialist to be brought if necessary directly to the patient. The ideal of the coordinating institutions will be always the patient as focus of medical knowledge, in opposition to the conception of him as a theatre for the activities of medical investigation. The care of the sick will include general medical and surgical treatment, eye, ear, nose and throat diseases, pediatrics, obstetrics and gynecology, venereal diseases, psychiatry and neurology. Research facilities will comprise laboratories for study and investigation in all kinds of diseases, mental and physical; and social service and hospital administration equipment.

Since all the institutions which are to cooperate in forming the Medical Centre have made large and valuable contributions to medical science and care in New York City, a sketch of their origin and development will be of interest.

Presbyterian Hospital was opened for occupancy on October 10, 1872. The illness of an old colored servant in one of New York's prominent families was, indirectly, the cause of its founding. Dr. Oliver White, a leading physician of that day, found this old woman sadly in need of good hospital care. When he tried, however, to place her in an institution of the proper kind, he found that she was barred because of her color. Indignant at such a state of affairs, Dr. White told his friend, James Lenox, that New York should have a hospital that would receive for care every person in need of its services. Mr. Lenox was heartily in sympathy with these principles, so, when the institution opened its doors, the wall bore conspicuously a bronze tablet declaring Presbyterian Hospital to be "for the poor of New York, without regard to race, creed, or color." This remains today the guiding principle of the institution. A further demonstration of loyalty to this ideal was given in 1895, when the great iron gates that guarded the hospital were removed as being out of keeping with the principle of its being open without restriction to all. The annual report for 1923, more than half a century after the founding of the institution, shows that the original ideal is still being followed, in that of the 255 beds, only thirty-five were allotted to private patients; 67 per cent. of ward treatments were given entirely without charge. The number of Roman Catholic and of Jewish patients exceeded that of any single Protestant denomination.

When Presbyterian was founded, it stood near what was then the upper end of Madison Avenue, directly adjacent to "Shanty Town," now a part of Central Park. The fashionable residents of Washington Square would drive up in their victorias and landaus to select their own vegetables from the Lenox Farm near by. Shanty Town was a disreputable and lawless district where squatters lived in huts and sheds built of cast off lumber and other

building materials, and made a precarious living as junkmen, hucksters, laborers and sometimes thieves. Their hovels were hideous, dirty, and unsanitary beyond description. The story, now a classic in New York's medical history, is told of a young physician who received a first call to visit a lady on Fifth Avenue. Wishing to make his initial professional appearance as impressive as possible, he dressed in his best, assumed his most dignified manner, and hastened to the bedside of the aristocratic resident of that famous avenue. The address proved to be that of forlorn hovel in which dwelt an old Irish woman suffering from chronic rheumatism. She was living in one room with her junkman son, and a large number of children, dogs, hens, and a goat. This picture is typical of the homes which surrounded Presbyterian at the time of its establishment. So it was indeed well placed for the great work it was to do.

A most important contribution to medical care and treatment made by the hospital was the establishment of one of the first training schools for nurses in the country. Dr. W. Gilman Thompson records the condition of the men's wards before trained nurses were available, when night "orderlies," usually convalescent patients, supervised the wards. The following are typical reports of such orderlies: "All patients slept good most part of night." "Nothing extra to report." "Everything quiet." "Rogers was noisy tonight. Whenever I turned my back he was out of bed." "There is nothing special to report this morning as all patients slept well and Cavalle slept like a young goat." "Cavalle slept well, but he kept shouting and whistling in this state, otherwise he was very quiet as he made no attempt to wander through ward. All other patients slept well." "Schneider died at 4:10 a. m. All others done well." Such reports speak for themselves; so Dr. Thompson recommended the establishment of a school of nursing, and on May 1, 1892, one was opened under the supervision of Anna Caroline Maxwell. This school has graduated nearly 900 nurses, who have played prominent parts in health service, not only from day to day, but in crises, such as the cholera epidemic in 1893; the Chickamauga typhoid epidemic in 1898; the terrible summer in 1901, when more than a thousand died in New York City from the heat; and in the World War, during which Presbyterian had more than 200 nurses in service. This hospital was also one of the first to establish a social service department. This was in 1904. In 1905 the Katie Geitz Diet Kitchen was established at the foot of Seventy-seventh Street to dispense milk to tuberculous patients, and warm, nourishing lunches to school children of the neighborhood. Hill Top Camp at Hawthorne Camp, New York, gave health improvement and recreation in 1923 to 110 "heart and tuberculosis" children.

Presbyterian was also a pioneer in introducing into America modern antiseptic methods. In 1876 a newsboy, who had fallen under an elevated train and been badly injured, was brought to the hospital. Dr. D. Bryson Delavan, then a young staff member, believed that amputation of the crushed leg, which seemed necessary according to the methods of the day, would result in death, so he asked for permission to try the then new Lister method. This was done and the boy recovered. In the same year, the first complete antiseptic treatment administered in America was performed by Dr. L. A. Stimson at Presbyterian Hospital. The case was a long neglected and very serious leg wound, but recovery was rapid and complete. The hospital brought to this country what is believed to have been the first Lister apparatus for operating under a carbolic spray. It was the first hospital in New York to use the insulin treatment for diabetes. In 1924 Dr. Alphonse R. Dochez, of the staff, announced his discovery of a serum that may revolutionize scarlet fever treatment.

Throughout its whole existence, from its foundation to the present day, the main consideration of the Presbyterian Hospital and its School of Nursing has always been the welfare of the individual patient, and it is this guiding ideal that forms the basis of the policy of the new Medical Centre, of which Presbyterian will be a unit.

COLLEGE OF PHYSICIANS AND SURGEONS

Occupying the central structure of the Medical Centre with the Presbyterian Hospital will be the College of Physicians and Surgeons of Columbia University. Its relation to the hospital has already been outlined. In 1807 the need of a well organized and well equipped medical college for New York was felt so strongly that the newly organized and very active Medical Society of the County of New York, which already possessed the power of examining students and granting licenses for practice, applied to the Legislature and to the Regents of the State University for incorporation as a college. A charter, dated March 12, 1807, was promptly granted by the Regents, establishing in the City of New York, the College of Physicians and Surgeons, "for the promotion of medical science and diffusing the knowledge of the healing art."* The first president was Dr. Nicholas Romayne, to whose efforts the establishment of the College was largely due. He was a graduate in medicine of Edinburgh and had studied in Paris and Leyden. The College opened in November, 1807, with an enrollment of fifty-three students, in a house in Robinson Street, now Park Place. The annual course was of four months' duration, supplemented by optional lectures. At least two years of study were expected before graduation. The years 1811-1826 were marked by some internal dissensions, which were adjusted by reorganization by the regents.

In the year 1813 an event of importance occurred in the absorption by the College of the medical faculty of Columbia College, a union which more than doubled the number of instructors and increased the teaching strength and prestige of the institution. The College now moved into quarters on Magazine, now Pearl Street, and soon afterwards to a house on Barclay Street, which building, with additions, served as headquarters for the next twenty-four years. Next it acquired possession of the famous botanical garden of Dr. David Hosack, covering the section now included between Forty

*F. S. Lee: *History of the School of Medicine.*

seventh and Fifty-first Streets on Fifth and Sixth Avenues. It was supposed that this would prove a valuable aid in the study of materia medica, but these hopes were disappointed, and the garden was transferred to Columbia College. In 1837 the College moved to a larger and more suitable building in Crosby Street. At this time optional spring and autumn courses were inaugurated, and, through the instigation of Dr. Willard Parker, clinical instruction in the College building as supplementary to beside instruction in the hospitals was instituted and has since remained. In 1856 the College was again moved, this time to the corner of Fourth Avenue and Twenty-third Street. Soon afterwards, under the presidency of Dr. Edward Delafield, it took an important and long needed step —alliance with Columbia College. This was preceded by a separation, by mutual agreement and legislative action, from the Regents of the State University. Now for the first time the trustees had the powers of granting degrees and of appointing their own officers. The title of College of Physicians and Surgeons was retained, but the institution was thereafter known officially as the Medical Department of Columbia College.

SLOANE MATERNITY HOSPITAL AND VANDERBILT CLINIC

In 1878 the first laboratory was established through the efforts of the Alumni Association. In 1884 William H. Vanderbilt made the splendid donation to the College of the land on Fifty-ninth Street, where it now stands, and $300,000 besides for the erection thereon of new buildings. Soon afterwards Mr. and Mrs. William D. Sloane proposed to build and maintain the Sloane Maternity Hospital, now the Sloane Hospital for Women, which will be housed in the same building of the new Medical Centre as the Presbyterian Hospital, and the College of Physicians and Surgeons. The Sloane Hospital was to be under the immediate direction of the professor of obstetrics, and was to furnish free obstetrical service and opportunity for practical instruction. At the same time the four sons of Mr. Vanderbilt gave $250,000 for a third building, the Vanderbilt Clinic, to serve as a free dispensary and home for the college clinics. The College building was completed and dedicated on September 29, 1887, and the other two buildings on December 29th of the same year. Through further generous gifts of Mr. and Mrs. Sloane, more land was purchased for an anatomical building, laboratories were added to the College building, the Clinic was doubled in size, and the Maternity Hospital enlarged and its capacity more than doubled.

The College year had by this time been lengthened a number of times, another year was added to the two years' course, the faculty was increased and new courses added, and demonstrative, practical and experimental work greatly augmented by new apparatus, instruments, models, museum specimens, and other necessary equipment. The College was thus enabled to take a position of leadership in medical science, and it has ably maintained this position throughout its progress up to the present time.

BABIES' HOSPITAL

The Babies' Hospital, now located at 135 East Fifty-fifth Street, first opened its doors in 1887 in a twenty foot dwelling house at 161 East Thirty-sixth Street. It was the first hospital in America designed exclusively for sick infants, and it had eight beds. The early years were difficult ones, yet the progress toward an ideal was continuous. On June 23, 1887, the Hospital was incorporated, and a house on East Thirty-sixth Street was finally rented, after some complications, and work begun there in June of 1888. This venture, however, proved rather unsuccessful, and the whole project was threatened with dissolution, until Dr. L. Emmett Holt was persuaded to take charge of the medical work, a position in which he served with notable success until his death in 1924. In 1889, the present home of the hospital was acquired, and from that time until today the success and scope of the work has steadily increased. A Training School for Nursery Maids was organized in the wards of the Hospital in 1890, and in 1891 an out patient department was opened. In the same year, Dr. and Mrs. A. Blair Thaw offered to erect a permanent summer home at a cost of $10,000 in memory of their children. Land for this was purchased at Oceanic, New Jersey, and a cottage built; other cottages were donated by Mr. and Mrs. J. Hooker Hamersley, William F. Havemeyer, and Edward Kemp. These buildings, with the Nurses' Home built by the Cribside Committee in 1889, form a complete summer plant accommodating fifty children. In 1894 a house adjoining on Lexington Avenue was rented and connected with the Hospital.

In 1896 Dr. Christian A. Herter established and equipped a pathological laboratory and for several years contributed largely to its support. By 1900 the Hospital buildings were found to be altogether too small and unfitted for the growing work, and, through a campaign and the generosity of John D. Rockefeller, $200,000 was secured for a new building. This was constructed on the same lot, the hospital work having been temporarily transferred to another location, and was ready for occupancy in September of 1902. In 1905 the house adjoining was purchased for a dormitory for nurses, but in 1907 this was demolished and a greatly needed addition to the Hospital built in its place. Since that time the work of the Babies' Hospital has continued to increase so rapidly that these quarters are much too small, so a new building will be constructed near the main group of Medical Centre.

NEUROLOGICAL INSTITUTE

Across Fort Washington Avenue from the main group of buildings will be the Neurological Institute, now on East Sixty-seventh Street. Dr. Edwin G. Zabriskie, secretary of the Institute, has outlined its history in a recent article. During the month of March, 1909, certain ideas that had long been quietly gathering force in the minds of several medical men of New York City, were presented to a small group of public spirited and influential men who had been asked to listen to a statement of the need for a hospital that could adequately care for those suffering from nervous or mental disorders. The purpose of this hospital as set forth embodies three

great principles. First, the principle of providing adequate dispensary and hospital facilities for the diagnosis and treatment of the many types of nervous and mental disorders among what might be called the great class of people in moderate circumstances, who were unable to afford the cost of expensive private sanitariums, yet shrank from entering the wards of general hospitals. . . . Second, the principle of educating the community through broadcasting the fact that assistance can be provided for those suffering from the disabling mental problems and nervous troubles constituting the great class of neuroses by meeting these problems openly. Third, the principle of intensive study of the many baffling problems concerning the nature, the cause, the origin, the treatment and the prevention of the diseases which constitute this special branch of medicine.

After the War, when the Institute settled down to its normal activity after demobilization, the older members of the Medical Board early in 1920 decided to pass the burden of active direction on to the men they had trained to succeed them. Thereupon a new Board was appointed by the trustees consisting of Foster Kennedy, Walter Timme, and Edwin G. Zabriskie, with Charles A. Elsberg still remaining as surgeon. Eventually Frederick Tilney of Columbia, was invited to join the staff, and in this way the Institute was able to bring together representatives of two great teaching institutions in New York City on its Board. Increased activity in scientific research followed, made possible by special grants from the Commonwealth Fund. In the meantime, the intensive study of maladjusted children had been undertaken, and the classification clinic founded as an auxiliary department where adolescents of both sexes might be studied and guided in their future development.

Dr. Zabriskie states that "the history of the Institute is replete with attempts to lead the way in the relief of suffering, in the education of laity and physicians, and in scientific advance. Perhaps the most important decision in its life history has recently been made through affiliation with the Columbia-Presbyterian Medical Centre, where close contact with other branches of medicine and unlimited opportunity for scientific research will be available."

PSYCHIATRIC INSTITUTE

Adjacent to the Neurological Institute will be located the New York Psychiatric Institute and Hospital. In 1895 the State Hospital Commission secured the passage of a law providing for the establishment of The Pathological Institute of the New York State Hospitals. The plan was to develop the Institute as a central pathological laboratory and research department for the New York State Hospital System. Dr. Ira Van Gieson was appointed Director, and quarters for the new Institute were provided in the Metropolitan Life Insurance Building, 1 Madison Avenue, New York.

The Institute was conducted at this location until 1901, when Dr. Van Gieson resigned and the laboratory was closed until 1902, when the Institute was reorganized and moved to Ward's Island where access could be had to the clinical material of the Manhattan State Hospital. Dr. Adolf Meyer was appointed director and the name was changed to the New York Psychiatric Institute. The activities of the Institute were broadened to include work in clinical psychiatry, neuropathology, chamistry, serology and allied subjects. Dr. Meyer resigned in 1910 to accept the professorship of psychiatry at the Johns Hopkins Medical School, and was succeeded by Dr. August Hoch. In 1917, because of ill health, Dr. Hoch resigned and the present director, Dr. George H. Kirby, was appointed.

In 1920 the Legislature passed a bill authorizing the removal of the Institute from Ward's Island to a new location to be selected in New York City. The new plan calls for the development of a modern psychiatric hospital of two hundred beds, combined with an Institute with facilities for research and teaching in the general field of psychiatry. Special emphasis will be placed on the treatment of incipient and early mental disorders as well as the study and investigation of more advanced mental conditions. Special studies and investigations will be carried on in neuropathology, neuroanatomy, bacteriology, biological chemistry, serology, endocrinology, psychology and allied subjects. An important phase of the work will be the study and treatment of problem children both in the school and preschool age. It is planned to make the new hospital and institute an educational as well as a research and treatment centre, a place where information and expert advice may be obtained on all problems relating to mental health, where courses will be given for teachers and social service workers, in addition to providing instruction for medical students and postgraduate work in psychiatry for physicians. It is expected that the new institution will become one of the most active mental hygiene centre in the country.

"So it is," to quote Dr. Burlingame again, "that the medical sciences are developing along the lines of institutional cooperation, not competition; association, not consolidation; coordinated knowledge, but individual service; group service, but personal attention; with all health workers trained together. The days of the family practitioner are returning to New York—not as formerly when all of his information was personal—but as the coordinator of the knowledge possessed by a group of highly trained scientists. And once more the patient will be able to cast all of his health burdens upon a single man."

After a recent visit to the new Centre by Lord Dawson of Penn, physician to His Majesty the King of England, and Sir Arbuthnot Lane, the noted British surgeon, the latter made, in a letter of appreciation to Dr. Darrach, the following comments on the significance of the proposed work: "Please accept my most hearty thanks for giving me the opportunity of seeing the magnificent work that is being done in the construction of the new buildings of the Columbia-Presbyterian Hospital. It was a great joy to me to see how medicine is going to develop in New York and to feel the pride that the whole medical profession will experience when they learn of the monumental work you have done. It will do much to elevate the whole position and standing of our profession among the professions of the world, and to make the public realize what efforts are being made to secure to them health and happiness."

Letters to the Editor.

EDITORS OF THE EXTRA PHARMACOPŒIA

London, *December 7, 1925.*

To the Editor:

We received a few days ago a copy of your issue for November 18th, in which there is a short notice of the *Extra Pharmacopœia* on p. 631. In the last paragraph there is an unfortunate error with regard to the death of one of the editors. The editor who died a short time ago was Dr. W. Wynn Westcott. We communicated with the surviving editor, sending him the notice, and in thanking you for same, he asks that you will be good enough to insert a note correcting the mistake.

As a matter of fact Dr. W. H. Martindale has done the editing for several editions, as for some years Dr. Westcott has not taken much part. The mistake which has occurred suggests the words of a celebrated author of your country that the report concerning Dr. W. H. Martindale's death is "greatly exaggerated."

H. K. Lewis & Co., Ltd.
H. L. Jackson, Director.

News Items.

Virginia Medical School.—The amount of $700,000 has been granted by the General Education Board to the University of Virginia for buildings and equipment of the medical school.

Fellowship Reward.—Dr. William E. Gye has received the annual fellowship award established by London University for the graduate doing the most for the advancement of medicine in the last five years.

Medicinal Use of Alcohol.—The National Woman's Christian Temperance Union has passed a resolution that the sale and prescription of alcoholic beverages as medicine should be unlawful, and that legislatures should be commended which have passed laws forbidding such sale and prescriptions.

Pittsburgh Skin and Cancer Foundation.—A report of the second year of the establishment of this foundation shows the attendance doubled; of 557 new cases, 410 were in the dermatological and 93 in the cancer department. A study is being made of the relation between gastrointestinal and dermatological conditions.

Rockefeller Studies.—At present the Rockefeller Institute for Medical Research is studying cases of nephritis, chickenpox, acute pulmonary infections, rheumatic fever, and cardiac disease. Physicians wishing further information regarding the acceptance of such patients should communicate with the Institute.

Anniversary Celebrated.—A banquet was recently held in Baltimore commemorating the one hundred and eighteenth anniversary of the founding of the School of Medicine of the University of Maryland. The medical school was the fifth to be established in this country. Dr. Arthur Shipley, professor of surgery, was toastmaster.

Hospital News.—The Western Suburban hospital of Oak Park, Illinois, is to erect a $350,000 addition.

St. Bernard's Hospital of Chicago has become affiliated with Loyola University, and has reorganized its staff.

The new building of the Englewood Hospital, Englewood, New Jersey, built at a cost of one million dollars, was opened November 30th. The old building will be used as a maternity ward.

The Knickerbocker Hospital of New York, is planning to raise $200,000 for an emergency building.

The Deaconess Hospital of Cincinnati, Ohio, is conducting a campaign for $500,000, for new buildings.

Funds for Rush Medical College.—The alumni of this institution, under the leadership of Dr. Ralph W. Webster, of Chicago, are endeavoring to raise $250,000 as a contribution toward the general development funds of the University of Chicago.

Rawson Laboratory Dedicated.—The Rawson Laboratory of the Rush Medical College has recently been dedicated. The building contains libraries, classrooms, examining rooms, laboratories, small operating rooms, and quarters for the Central Free Dispensary.

Gift of Old Instruments Requested.—The Dispensary Boat of China asks for instruments, apparatus, surgical supplies, and drugs, for use in its trips back and forth among the villages of the Grand Canal of China. Contributions will be received by the China Medical Boat Fund, 383 Bible House, New York.

Medical Practice in the Philippines.—The Manila Medical Society has adopted resolutions against the exemption from examination by local examiners of men holding certificates from the National Board of Medical Examiners. It is felt that physicians from other countries should take special courses before beginning practice in the tropics.

Memorials to Doctor Hunter.—The fund subscribed as a memorial to the late John Irvine Hunter, of Australia, is to be used for six objects,—a portrait for the University of Sydney; a bust for the medical school of the university; an annual oration with the award of a medal; the endowment of a library; the establishment of the John Irvine Hunter Research Laboratory, for clinical research; and the establishment of annual scholarships for research workers in the laboratory. Research will be encouraged on diseases commonly found in Australia, with special reference to children's diseases.

Gifts and Bequests.—The Hospital for Joint Diseases, New York, has received a seaside home for convalescent patients, at Far Rockaway, Long Island, and an endowment fund for its maintenance, making a gift of $1,250,000. The donor was Albert M. Heinsheimer, a member of the board of managers.

The following New York hospitals,—Broad Street, Mount Sinai, New York, Mount Lebanon, Presbyterian, and St. Vincent's, have been bequeathed $30,000 each in the will of the late Mrs. Mathilde G. Sterne.

The will of the late William Hull Wickham provides $10,000 each for St. Vincent's Hospital, the Home for Incurables, Roosevelt Hospital, New York Dispensary, and the Southside Hospital at Bay Shore.

The will of the late Harry Evans of New York provides $305,000 for the Associated Hospitals and $610,000 for the hospital conducted by the Servants for Relief of Incurable Cancer.

Personal.—Dr. J. Victor Haberman has been appointed special consultant in neuropsychiatry to the United States Employees' Compensation Commission.

Dr. Isaac A. Abt has been appointed attending physician in diseases of children at St. Luke's Hospital of Chicago.

Dr. Seymour Basch has been appointed professor of clinical gastroenterology at the Polyclinic Hospital, New York.

Three new directors have been elected for the Physicians' Home,—Dr. George David Stewart, Dr. George Dow Scott, and Dr. Ward Bryant Hoag, all of New York.

Dr. Frederick H. Falls, of the Iowa State University, is to be professor of obstetrics and gynecology, and head of the department, at the University of Illinois College of Medicine, Chicago.

Dr. Edmund B. Piper succeeds the late Dr. John Cooke Hirst on the staff of the Philadelphia General Hospital.

Dr. T. A. B. Denison, superintendent of the Lakeside Hospital of Cleveland, has resigned to enter private practice.

Dr. Carl Hedblom of the University of Wisconsin, has received an appointment as professor of Surgery at the University of Illinois College of Medicine.

Dr. Clarence H. Harris has been appointed health officer of Louisville, Kentucky.

Dr. Alfred J. Asgis of New York City delivered a lecture before the Dental Hygienists Association of New York City on Public Stomatology and Ulotropsis, at the New York Academy of Medicine, on December first. He also spoke in Philadelphia, before the Eastern Dental Society, on Pyorrhea Alveolaris, Dentoalveolar Stomatitis and Ulotropsis, on Thursday, December third.

Society News and Notes.

On December 18th Professor Wolfgang Köhler of the University of Berlin gave the annual address before the New York Society for Clinical Psychoatry, at the Academy of Medicine. Prof. Köhler's subject was the Psychic Life of Apes.

* * *

On January 12th, at 4 p. m. at the New York Academy of Medicine, Paul Klapper, Ph.D., Dean of the School of Education of the College of the City of New York, will speak on Mental Tests—Their Uses and Interpretation. On January 19th at the same place and the same hour, Stanley P. Davis, Ph.D., Executive Secretary of the New York State Committee on Mental Hygiene, will read a paper on Applying Mental Hygiene to the Community.

* * *

The Library of the New York Academy of Medicine will open on January 15th an exhibit on the history of appendicitis. This exhibit will be supplementary to the address to be given on January 28th before the Section of the History of Medicine of the Academy by Dr. Robert T. Morris on the Evolution of the Subject of Appendicitis. One of the features of this exhibit will be a chronological bibliography covering the years from 1739-1899 inclusive, compiled by Dr. Edebohl and presented by him to the Library.

For the first time in twenty-four years the State Conference of Charities and Correction was held in New York City, December 8th-11th, at the Hotel Roosevelt. Among the speakers were Dr. Amos T. Baker, Dr. Matthias Nicoll, Jr., State Commissioner of Health, Dr. C. E. A. Winslow, and Dr. Haven Emerson.

* * *

The Society for the Prevention of Cruelty to Animals has announced that Humane Sunday in 1926 will be April 11th, the first Sunday after Easter. "Be Kind to Animals Week" will extend from April 11th to 17th.

* * *

Dr. Israel Weinstein lectured on the Psychology of Insanity on the evening of Sunday, December 13th, before the forum of the Hebrew Educational Society.

* * *

The twentieth annual meeting of the Woman's Medical Society of New York will be held at the Hotel McAlpin, New York City, on Monday, March 29, 1926, beginning at 9:30 a. m.

* * *

The next annual meeting of the American Gynecological Society will be held on Thursday, Friday and Saturday, May 20-22, 1926, at the Red Lion Inn, Stockbridge, Mass.

* * *

The following officers for 1926 were elected at the recent annual meeting of the Royal College of Physicians of Ireland: Dr. T. Henry Wilson, president; Dr. W. A. Winter, vice president and censor; Sir John W. Moore, representative on General Medical Council; Dr. H. T. Bewley, treasurer; Dr. T. Percy C. Kirkpatrick, registrar; Mr. R. Phelps, librarian. Jane Elizabeth Waterson, M.D., M.R.C.P.I., of South Africa, was elected a Fellow of the College.

* * *

The American Association of Hospital Social Workers elected at its recent annual meeting the following officers for 1926: Mrs. Maida H. Solomon, of Boston, president;; June Lyday, of Iowa City, vice president; Margaret L. Wirt, of Boston, secretary-treasurer; other members of the Executive Committee, Mary C. Jarrett of Boston, Katherine Moore of Chicago, Helen L. Myrick of Chicago, and Mrs. Margaret J. Powers of New York.

British medical and scientific societies are enjoying this season an unusual number of interesting lectures. The Bradshaw Lecture of the Royal College of Surgeons of England was delivered November 11th by James Sherren, C.B.E., F.R.C.S., on the subject of Gastrojejunostomy. The Thomas Vicary Lecture was delivered on November 18 by Prof. William Wright, D.Sc., F.R.C.S., on the Medieval Conception of the Anatomy and Physiology of the Central Nervous System. The first of the series of Chadwick public lectures was given on October 22d by Sir Lawrence Weaver on the subject of Cottage Problems, Rural and Suburban; Recent Developments; on October 30th and November 6th at the Sanitary Institute, London, Dr. Howarth, Medical Officer of Health, lectured on the Control of the Food Supply; Prof. E. P. Cathcart of Glasgow University spoke on the Food Question in several townships during the latter part of October. Dr. J. D. Rolleston lectured on October 28th at the Royal Institute of Public Health on Prevention and Arrest of Diphtheria.

* * *

Dr. Jaques Forestier of Paris and Aix-les-Bains is lecturing in New York and other large cities of the country on lapiodol, which he was among the first to use. Dr. Forestier is here in the interests of the *Union Nationale des Associations d'Etudiants re France.* Other recent foreign visitors of note in New York recently were Dr. Mario Julia of Porto Rico, who is interested in neuropsychiatry; Dr. S. Zlattogoroff, of Leningrad, director of the Bacteriological Institute of Kharkov; and Prof. Wolfgang Köhler, of the University of Berlin.

* * *

The Medical Association of the Greater City of New York met on December 21st at the Academy of Medicine. Dr. S. Adolphus Knopf read a paper on Birth Control—Sanitary, Medical and Moral Aspects; Dr. Isaac Hartshorne spoke on Recent Progress in Treatment of Cataract; and Dr. Ellice M. Alger read a paper on Ocular Danger Signals.

* * *

The Clinical Society of Reconstruction Hospital met on December 17th. The program included a paper on the Pathology of Fractures of the Skull, by Dr. S. B. Cassassa, Assistant Medical Examiner of the City of New York, and presentation of cases by the staff.

* * *

The third lecture in the series of the Harvey Society was given at the New York Academy of Medicine on December 12th. Prof. Warren H. Lewis of the department of physiological anatomy at Johns Hopkins Medical School spoke on the Origin of Macrophages and Epitheloid Cells from Mononuclear Blood Cells.

The midwinter session of the American Electrotherapeutic Association and affiliated Eastern societies, comprising the New York Electrotherapeutic Society, the Philadelphia Electrotherapeutic Society, and the New England Association for Physical Therapeutics is being held at the New York Academy of Medicine, January 6th and 7th. There will be a clinical session on Friday, January 8th, at the Reconstruction Hospital and at the Beekman Street Hospital. On Wednesday, the 6th, Dr. William D. McFee, of Haverhill, Mass., speaks on Physiotherapy in the Treatment of Arthritis; Dr. Frank B. Granger, of Boston, on Subdeltoid Bursitis; Dr. William B. Snow, of New York City, on Treatment of Local Septic Infection; and Dr. William T. Johnson, of Philadelphia, on the Value of Static Currents in Preventing Baldness. At 6:30 p. m. there is an informal dinner at the City Club. In the evening occurs the stated monthly meeting of the New York Electrotherapeutic Society, at which Dr. Morris Fishbein, editor of the *Journal of the American Medical Association,* speaks on the Council of Physical Therapy; Dr. William C. Phillips, of New York, president-elect of the association, will also be heard. These papers are to be followed by a symposium on diathermy, in which the chief speakers will be A. Mutscheller, Ph.D., of New York, whose paper is on the Physics of High Frequency Currents; A. P. Mooradian, also of New York, who demonstrates the Construction of High Frequency Apparatus; and Dr. Frederick DeKraft, of New York, whose paper is on the Clinical Action of Diathermy. On Thursday morning at 9:30 there will be held a symposium on radiotherapy, in which Dr. Sinclair Tousey, of New York, will speak on the Dangers of X Rays; Dr. J. Douglas Morgan, of Philadelphia, on Small Versus Large Doses of Deep X Ray Therapy; Dr. Mary L. H. Arnold Shaw, of New York, on X Ray Therapy of Uterine Hemorrhage and Fibroids; and Dr. G. Allen Robinson, of New York, on Radium Therapy. In the afternoon at 2 Dr. William H. Schmidt, of Philadelphia, will read a paper on the Surgical Uses of High Frequency Current; Dr. G. Betton Massey, of Philadelphia, will speak on Wave Currents in Intestinal Inactivity; Dr.

Richard Kovacs, of New York, on Physical Therapy in Chronic Poliomyelitis; and Dr. Frank T. Woodbury, of New York, on the Present Status of Phototherapy. The clinical session on Friday morning at the Reconstruction Hospital will begin at nine, and will include interesting demonstrations by Dr. Kovacs and Dr. Edward C. Titus, and the presentation of cases under active physiotherapy by Dr. Seth H. Milliken, Dr. William V. Healey, and Dr. Edwin A. Spies, of the attending staff. On Friday afternoon at two a session will be held at the Beekman Street Hospital, 117 Beekman Street, which will include a demonstration of physiotherapy in the treatment of fractures by Dr. Titus and Dr. Fenton Taylor, visiting surgeon. Registration cards may be obtained by all legally licensed physicians by personal application at the time of the session.

The January schedule of meetings at the New York Academy of Sciences includes that of the Section of Biology on January 11th; the Linnaean Society of New York on January 12th; the Torrey Botanical Club on the same date; the Brooklyn Entomological Society on January 14th; the New York Microscopical Society on January 15th; the New York Entomological Society on January 19th; the New York Mineralogical Club on January 20th; the Aquarium Society on January 22nd; the Section of Anthropology and Psychology of the New York Academy of Sciences on January 25th, the American Ethnological Society on the same date; the Linnæan Society on January 26th; and the Torrey Botanical Club on January 27th.

* * *

Meetings held during the latter part of December at the New York Academy of Medicine include the stated meeting of December 17th, arranged in cooperation with the Section of Laryngology and Rhinology, when Dr. Thomas J. Harris read a paper on End Results of Tonsillectomy with Special Reference to the Legal Responsibility; the Section of Genitourinary Surgery on December 16th at which the program was contributed by the urological staffs of St. Luke's and the Woman's Hospitals; Dr. John A. Taylor read papers on Multiple Fractures of the Pelvis and Rupture of the Bladder, and Tumor of the Prostate; Dr. George F. Hoch spoke on an Unusual Rupture of a Pyonephrotic Kidney, and Calcification of Ovary as an Extraurinary Shadow; Dr. Francis E. DuBois read papers on Papilloma of the Bladder with Surgical and Postoperative Complications, and a Case of Herpes of the Bladder; and Dr. Henry G. Bugbee spoke on Some Interesting Problems in Kidney Surgery. The Section of Orthopedic Surgery met on December 18th. The program consisted largely of the presentation of cases by Dr. Abraham Urevitz, Dr. Benjamin Koven, Dr. Morris T. Koven, Dr. Henry H. Kessler, Dr. Carl R. Keppler, Dr. Charles Dwight Napier, Dr. Walter Truslow. Dr. Joseph B. L'Episcopo, Dr. Jacques C. Rushmore, and Dr. Herbert C. Fett; the paper of the evening was on Synovectomy in Infectious Arthritis, by Dr. Paul Swett, of Hartford, Conn. The Section of Ophthalmology met on December 21st. Cases were presented by Dr. Thomas H. Curtin, and papers read on Protein Therapy in Practice, by Dr. Ben Witt Key; Use of Uveal Pigment in Synpathetic Ophthalmia, by Dr. Alan C. Woods, of Baltimore; Some Special Features in the Lens Antigen Protein Treatment, by D. A. Edward Davis. The Section of Obstetrics and Gynecology met on December 22. Case reports were given by Dr. S. Krell and Dr. Armitage Whitman; Dr. Harbeck Halsted read a paper on Full Term Ectopic Pregnancy.

* * *

At the last meeting of the American Stomatological Association held in New York City on November 16, 1925, the following officers were elected for the year 1925-1926: President, Dr. Weston D. Bayley, of Philadelphia; president-elect, Dr. George Reese Satterlee, of New York; first vice-president, Dr. Joseph Colt Bloodgood, of Baltimore; second vice-president, Dr. Oliver T. Osborne, of New Haven; treasurer, Dr. Robert H. Rose, of New York; secretary, Alfred J. Asgis, D.D.S., of New York.

* * *

On the evening of December 21st at the Waldorf Astoria the New York Academy of Sciences gave its annual dinner, followed by the annual meeting. The first address of the evening was by Prof. Ernest W. Brown, of Yale University, on the Prediction of an Eclipse. A very interesting motion picture was shown. The second address was given by Prof. Charles P. Berkey, of Columbia University, on the subject of the third Asiatic expedition to Mongolia. Prof. Berkey is a member of the Roy Chapman Andrews Expedition into Mongolia, and has recently returned from the 1925 expedition into the Bobi Desert. The lecture was illustrated by lantern slides and moving picture films.

The Travel Study Club of American Physicians has just announced the itinerary of its 1926 study tour. Those making the tour will sail from New York City, Saturday, June 12th, on the Stavangerfjord, due to arrive at Bergen on the 21st. The countries visited will include Norway, Sweden, Denmark, Germany, Switzerland, France and England. Returning, tourists will sail from Southampton, Saturday July 31st on the Cameronia, due to arrive in New York on August 8th. A short tour from July 9th-24th has also been arranged. The cost of the main tour will be $985; with Italian extension, $1,145; short tour, $725. Medical points of interest to be visited are the University of Christiania, at Oslo, Stockholm, with the Sabbatsberg Hospital, the Seraphin Hospital, Maria Hospital, Garrison Hospital, and the Radium Institute; Copenhagen, with the Finsen Light Institute, and the Bispjere and Riks Hospitals; Hamburg, with the Eppendorfer Krankenhaus, St. Georg Krankenhaus, and Institut für Schiffs und Tropenkrankheiten; Cologne's Academy of Practical Medicine; the Universities of Heidelberg, Strassbourg, Zurich, and Berne; the Cantonal Krankenhaus at Zurich; Rollier's Clinic for Crippled Children at Leysin; in Paris, the Hotel Dieu, and the Hospitals of Saint Louis, the Salpêtrière, de la Pitié, Pasteur Institute, Academy of Medicine, and School of Medicine; in London the Hospitals of St. Bartholomew, St. Thomas, and others, and many societies and institutions.

* * *

The adoption of the recommendations of the Special Committee on Nursing of the Medical Society of the County of New York constitutes the first really decisive step taken by the profession to remove the artificial obstacles placed in the way of the recognition of training schools today. Every doctor and hospital feels the shortage of nurses for home and institutional care. The conviction is general that this is due in large measure to the arbitrary attitude of the State Department of Education in the matter of academic and domiciliary details.

The plan accepted by the New York County Society calls for the regulation of nursing education in the Metropolitan district by the official medical organizations of the Greater City. It is in the capacity of deputy to the doctor that the nurse serves. The physician should have the privilege accorded every group of deciding what the qualifications of his assistants shall be.

Acting upon this premise, a Joint Committee representing the five county societies of the city will formulate a set of minimum standards for the guidance of training schools and will certify all institutions that comply with its requirements irrespective of whether they enjoy state approval or not. While the minutiæ of the project are yet to be worked out, it is hoped to give an impetus to nurse education which will assure a constant and adequate supply of competent nurses in our city.—*N. Y. Medical Week.*

Book Reviews

PULMONARY TUBERCULOSIS

Modern Methods in the Diagnosis and Treatment of Pulmonary Tuberculosis. By R. C. Wingfield, M.B., M.R.C.P., Medical Superintendent, Brompton Hospital Sanatorium, Frimley, England. New York: Paul B. Hoeber, Inc., 1925. Pp. 134.

This practical little book describes in ten chapters our present methods of dealing with pulmonary tuberculosis. In the first chapter, which is entitled "Tuberculosis in Its Relation to the Individual and the Nation," the statistics refer only to the mortality of the disease in England and Wales. They show that in England the highest mortality is during the first five years of life, which corresponds with the conditions prevailing in all countries where careful statistics are kept.

A somewhat surprising statement is made in this chapter when the author maintains that active tuberculosis of the lungs is compatible with a useful life of the ordinary length, but that in most cases life must be lived under special conditions. By active tuberculosis we usually understand a condition which requires absolute rest, and unless this is rigorously observed the ordinary length of life is bound to be shortened.

Under diagnosis the author first reviews the well known symptoms. He deprecates, and justly so, the cutaneous and intracutaneous tuberculin tests, since they cannot give any information as to the size or activity of the lesions, nor as the author might have added, as to their locality. Complementary fixation test he also considers as of doubtful value. Concerning the results of physical examination, while appreciating its value in early diagnosis, he comes to the same conclusion at which many physicians have arrived, namely, that "even in a case of well advanced pulmonary tuberculosis with positive sputum, physical signs of the lung lesion may be very slight or even completely absent." He attaches to the x ray picture a great deal of value if it is correctly interpreted.

In chapter 3 he makes a classification of active pulmonary tuberculosis as follows: a, miliary; b, bronchopneumonic; c, pneumonic. The chronic types he divides into the fibrocaseous, fibroid and pleural types. He precedes his chapter on treatment with the following terse pronouncement: "The patient's social, financial and home conditions must be accurately assessed, for his treatment, which may take five years or more, must be adapted to suit his environment." He then quotes Bushnell's maxims, "For tuberculosis we prescribe not medicine but a mode of life."

The author considers the sanatorium the place best adapted for regaining resistance, consolidating this gain, and educating the patient. Although admitting that of the three sanatoria—the Trudeau institution in the Adirondacks, the Frimley and the Medhurst—the American institution shows the best afterresults, he favors graded labor which is not used to any appreciable extent in the Adirondacks. He gives a complete description of Patterson's work at Frimley, which consists in carrying weights, hoeing, digging, trenching, etc. Tuberculin as a curative agent he believes "is indicated in those cases in which the ordinary methods for increasing the natural immunity to the required pitch have failed."

Pneumothorax, thoracoplastic operations and phrenicotomy are given brief consideration. The author goes very thoroughly into symptomatic treatment although nothing new is offered. Under the treatment of hemoptysis we find the following statement to which we might take exception: "If the hemoptysis continues and death from actual loss of blood seems imminent, the possibility of an artificial pneumothorax must be considered." Surely, it would be better not to wait until death seems imminent before considering the advisability of pneumothorax. Pneumothorax should be tried before, and in the meantime ligation of the upper and lower extremities near the thorax by means of tight bandages should be resorted to. This latter method the author seems to have entirely overlooked.

Aside from this little criticism, some unfortunate printing mistakes, as, for example, "Sangman" instead of Saugman, and the constant use of the word "tubercular" instead of tuberculous, the book must be considered a valuable handbook, particularly for the general practitioner who may not be quite familiar with the latest methods of phthisiotherapy.

TONSIL ENUCLEATION

Submucous Endocapsular Tonsil Enucleations. Excerpts from Clinics of C. C. Miller, M.D. Chicago: The Oak Press, 1925. Pp. 1-218.

The ideal tonsil operation, or at least the one to be accepted by most of the operators for the majority of cases and the one that would minimize both complications and sequelæ, such as hemorrhage, infection, cicatricial contractions, etc,—is still a consummation devoutly to be wished, and who knows how far from attainment. We are all on the *qui vive* for such an ideal, and it was with a lively sense of expectation that we approached the review of this work, alas! to be sadly disappointed as soon as we waded through the first few pages. This disappointment grew upon us the deeper we got into the substance of this rambling, incoherent and unsystematized recital of a new operative procedure that is to replace our old methods.

The extremely vague description of the author's submucous resection of the tonsil in its capsule that does not seem to be based on any clearly defined anatomical or pathological data, occupies a few pages, most of the rest of the book being devoted to an emphatic repetition of the elementary and the very obvious in tonsil surgery that is to be found in any of our textbook presented in *readable* English, and a hodge podge on blood transfusion, theory of fermentation, germs of putrefaction, and what not.

We doubt greatly whether the author has contributed in any measure to the solution of those perplexing problems that weigh so heavily on the mind of the honest, conscientious tonsil operator.

The absence of a paged table of contents and of an index detracts greatly from whatever little value the book may contain for some readers.

ELECTROCARDIOGRAPHY

Electrocardiografia. Esterdio teoricopractico del Electrocardiogram y de sus principales applicaciones clinicas. By Dr. Tiburcio Padilla. Con 507 figunas. Buenos Aires, 1924. La Semana Medica.

This monograph of 670 pages is a very comprehensive presentation of the subject of electrocardiography. The author, who is a professor at the University at Buenos Aires, has fashioned a scholarly and masterful treatise. A well chosen bibliography of sixty-three pages gives evidence of the breadth of his reading. There are over five hundred illustrations, mostly original and well reproduced. The arrangement of the material follows the conventional plan. Chapters are devoted to the anatomy and physiology of the conducting system, to a description of the instrument, and the normal electrocardiogram and its physiological variations. Then follows a detailed study of the cardiac irregularities. Among other things, Padilla verifies the work of American authors on the significance of aborization block. As a comprehensive review of electrocardiography in its theoretical and practical aspects, this volume will take first rank in the Spanish literature.

THE HIGH FREQUENCY CURRENT IN OTORHINOLARYNGOLOGY

La Haute Frequence en Oto-Rhino-Laryngologie. Par Leroux-Robert, ancien assistant d'Otorhinolaryngologie de la Salpetrière. Paris: Masson & Cie, 1925.

Published as one of the Masson series, *Medecine et chirurgie pratiques,* this little volume discusses the application of the d'Arsonval-Bergonié modality to various affections of the ear, nose, and throat. The physics of the high frequency current and its action in such varied forms as diathermy, effluviation, diathermy coagulation and fulguration, are discussed at length. The influence of the current on the sympathetic, on colloids, and on the circulation are taken as the basis of its application in such a range of morbid conditions as chronic laryngitis, dry otitis, tinnitus aurium, nasopharyngeal fibroma, sinus headaches, otalgias, and esophageal spasm. In an interesting preface d'Arsonval refers to his first presentation of this therapeutic agent in 1896, at l'Hotel Dieu which at that time was without electrical installation.

THE SPHENOIDAL SINUS

Le Sinus Sphénoïdal. Anatomie, Exploration, Chirurgie. By Georges Canuyt, Professeur de clinique otorhinolaryngologique, and Jean Terracol, chef de clinique Otorhinolaryngologique à la Faculté de Médicine de Strasbourg. Paris: Masson et Cie. Editeurs, 1925.

This well written and exceptionally well illustrated volume offers a practical handbook to the specialist in which are united the embryology and anatomy, the methods of examination, and the technic of endonasal surgery as far as it applies to the attack on what the authors refer to as the most distant and recondite as well as the most neglected of the accessory sinuses. Without subscribing unhesitatingly to this assertion, we must admit that Canuyt and Terracol have brought together the facts scattered in many single publications, in various languages, and at different times. The elaboration of the two routes of attack, the road of the meatus and that of the turbinates, respectively, is, in itself, a noteworthy contribution to a small but most important domain of surgery. The relation of morbid conditions in the sphenoidal sinus to ocular affections, particularly to retrobulbar neuritis with rapid or even *foudroyant* loss of vision makes the appearance of this work more than ever timely.

GENERAL MEDICINE

Ergebnisse der gesamten Medizin. Unter Mitwirkung hervorragender Fachgelehrten, herausgegeben von Prof. Dr. Th. Brugsch, Oberarzt der II. Med. Klinik der Charité in Berlin. Siebenter Band. 1. und 2. Heft, Mit 63 Abbildungen im Text, 2 farbigen und 10 schwarzen Tafeln. 3, und 4. Heft, Mit 73 Abbildungen im Text und einer farbigen Tafel. Berlin und Wien: Urban & Schwarzenberg, 1925, iv-596.

In their monograph, *The Climatotherapy of Tuberculosis,* A. Bacmeister and Frank Baur show that the old belief that mountain air is the only beneficial climatic treatment for tuberculosis is erroneous. They discuss the various elements that enter into the makeup of certain types of climate and their influences upon the tuberculous process.

G. Sultan and H. Ahrens give some valuable hints in the treatment of fractures and disclocations of all the bones in the body. H. C. Jacobaeus contributes a very complete treatise on a comparatively new maneuvre, thoracoscopy, giving the details of the technic of examination and of treating (cauterizing) pleuritic adhesions. F. Cumpertz is assigned the subject of the disturbances of speech encountered in children. A very complete and interesting monograph on the relationship of eczema and urticaria, giving all the theories advanced on the subject, is the work of E. Pulay.

The relationship between the medical profession and social hygiene is discussed in its various phases by C. Coerper. H. Sellheim discusses the results from the attempts at the simplification and improvement of the Abderhalden reaction, and as a result of his studies he expresses the hope of some day being able to attack the problem of cancer by way of the blood stream.

O. Strauss briefly reviews the subject of the diagnosis and therapy of cancer. In an article on the Roentgen Diagnosis of the Gastric and Duodenal Ulcer, F. M. Groedel and H. Lossen endeavor to erect the structure of pathological roentgen anatomy and pathologic roentgen physiology from the normal roentgen anatomy and roentgen physiology, thereby to place the roentgen symptomatology of the individual diseases, that has been evolved in an empirical manner, upon a scientific basis. P. Reckzeh discusses the clinical and experimental aspects of ankylostomiasis. Infantile tetany is described by E. Nassau. J. Zappert discusses the problem of the nervous child very exhaustively.

The article on suggestion and autosuggestion is the work of E. Raimann. The expert opinion of questionable mental conditions in criminal trials is amply discussed by W. Vorkastner. E. Kylin discusses the adrenalin blood pressure reaction and its clinical significance and maintains that this reaction is of great assistance in diagnosis. Nicotinism is the subject assigned to H. Kionka and he supplies a very good and instructive review. Typhus fever is the product of the pen of D. D. Pletnow, who gives a comprehensive résumé of the subject.

Medicoliterary Notes.

The edition for 1925, of the Medical Directory of New York, New Jersey and Connecticut, is just out. Those who use it for reference will be pleased to see that the list of hospitals in New York State, and also that of medical colleges, both of which have been discontinued since 1917, have been resumed. It is hoped that the next issue will include the list of other State and local institutions which formerly added to the directory's value as a reference work.

Two useful and interesting little books have recently been published by William Heinemann, of London, with an American edition of one from William Wood & Co. These are: *The Culture of the Abdomen: The Cure of Obesity and Constipation,* by F. A. Hornibrook (second edition), and *Sex and Exercise:* A Study of the Sex Function in Women and Its Relation to Exercise, by Ettie A. Rout (Mrs. Hornibrook). Both are written in popular style, particularly for lay reading, and are excellently illustrated.

* * *

An attractive little facsimile reprint is that of *Pictor's Tract of the Renal Calculus* (1557), with an English translation, by Dr. Charles Greene Cumston. The edition was limited to 400 copies. It is beautifully printed in the old type by Albert Kundig, of Geneva, Switzerland.

* * *

Much curious information about the vast human hive known as London, is contained in a statistical abstract issued by the City Council. Among many things, it is shown that there are not enough men to go around. The bachelors number 539,700, and the widowers 72,459, while there are 725,884 single women, and 223,615 widows. The number of husbands is 865,300, while the number of married women is 887,298. The total number of men is 1,477,459, and of women 1,821,797. London has a large appetite, consuming last year 480,520 tons of meat, poultry and provisions. Billingsgate Market sold 184,080 tons of fish. There was not a single death from smallpox last year. London's night schools were attended by 117,358 students. Institutional poor relief was given to 69,743 persons. . . . The resident population of the "city," the original nucleus of the metropolis and business centre, has now dropped from 128,128 in 1801 to 13,709, but the day population increased from 261,061 in 1881 to 436,721 in 1921. The London Council's total expenditure last year was 25,236,971 pounds sterling. There were 7,111 fire alarms last year, 2,292 of them were false. The fire damage was more than 900,000 pounds. There are 8,058 saloons in London. . . . There were 19,000 fewer marriages last year than in 1915.—*N. Y. Times.*

* * *

A pamphlet has recently been prepared by Smith, Kline & French, of Philadelphia, manufacturers of phosphates, on *Recent Studies Concerning the Metabolism of Phosphorus.* In the past decade physiological chemists have devoted much study to the function of phosphorus in the human body, and their recent findings have been extremely suggestive in regard to the relation of phosphorus compounds to fat assimilation, milk secretion, bone formation, etc. The metabolism of phosphorus is very directly associated with disease, so the above mentioned pamphlet will be of interest to physicians, since it covers in brief the work done on phosphate metabolism. Physicians may have copies of the pamphlet upon application to the Smith, Kline & French Co.

* * *

Dr. I. L. Broosilovsky, of Moscow, is the author of a pamphlet of unusual interest which has been received by medical friends in New York City. The title is the *Prevention of Diseases of the Nervous System and Standardization of Mental and Physical Labor.* Dr. Broosilovsky advocates "visas" for motherhood, based on an examination of all girls of seventeen on questions connected with motherhood and child care. He suggests as an excellent innovation "individual sanitary passports" based on a careful examination of every infant at registration of his birth. He makes a plea for health of mothers and proper home and school environment, education of adolescents to meet the crisis of puberty, and careful sex education. Taking as a premise that refraining from the sexual act does not bring about harmful results to the organism, he advocates deflecting all creative energy into the channels of physical culture and other wholesome distractions, and raising the awareness of youth to the importance working out of the creative instinct to the individual and to society, where the individual creative instinct, growing out of the idea of healthy and rational labor, will be the basis of individual and communal welfare.

* * *

Animals cannot be used as standardizers for the use of pharmaceutical preparations for man, writes Dr. Fritz Küts, Privatdozent für Pharmakologie, Leipzig, in an article in the *American Journal of Pharmacy.* The degrees of senstiveness of man and animals to particular drugs vary so widely as to make experiments tried on animals in many cases useless as applied to human physiology.

* * *

The Lord's Will, recently published by Henry Holt & Co., is a collection of American plays, by Paul Green, author of *No 'count Boy,* the play which won the Belasco cup in 1925. Mr. Green is a member of well known Carolina Playmakers, seen in New York during the holidays. *No 'count Boy* is included in the collection.

* * *

A whisper is used in the French army to test the hearing of recruits, according to a recent article in the *Lancet.* A candidate who cannot hear a whisper at the distance of eighteen inches is rejected, althought he may be accepted for auxiliary services if he can hear it at a distance greater than nine inches.

* * *

Mail Order Medical Frauds, is the title of an interesting and very informing article in the *Nation's Health* for November, by Rush D. Simmons, chief post office inspector of Washington, D. C.

* * *

Bombay, India, has extended its rent laws through 1928. This was done at the July session of the Legislative Council. The rent of business premises had been free from control since August 31, 1924, and control of house rents was to expire on December 31, 1925. It was shown, however, that, while rents of the better class of dwellings were falling, there had been practically no reduction in the rents of the working class houses.

* * *

Heredity and Culture as Factors in Body Build is the title of an interesting article in *Public Health Reports* for November 27, 1925, by C. B. Davenport and Louise A. Nelson, of the Carnegie Institution of Washington.

* * *

The British press reports that artificial sunlight baths have been installed at Drury Lane Theatre, London, for the benefit of the company and staff. These baths are free, and have a total radiation of 100,000 candle power. The installation was made under the supervision of Dr. F. Howard Humphris and Dr. Cecily Maude.

* * *

A recent valuable publication of the Child Study Association of America is entitled *The Child First Books;* a Study of the Best Picture and Story Books Available for the Preschool Child, prepared by Elsa H. Naumburg. Prof. Arnold Gesell, of Yale University, has written a foreword. The books listed are not confined to publications in the English language, but are drawn from those of Germany, France, Scandinavia, Czechoslovakia and other countries.

* * *

Robert Keable, the young English writer, who has been ill for some time in San Francisco, has gone again to Tahiti, taking with him garden and farming tools, seeds and plants, and chickens, and cats and canary birds for company.

* * *

A useful liaison exists between the Company of Fishmongers of London, and the local health authorities, reports the *Analyst.* When a batch of shell fish is to be condemned, the routine procedure of the health authorities is so slow that great hardship results to the food dealers. The health authorities, therefore, have recourse to the well known short method of twenty-four hour incubation of samples aseptically obtained from suspected shell fish for Bacillus Coli in suitable dilutions of bilesalt broth and litmus milk. Acidity and gas are taken to indicate the presence of the bacteria and the inference is drawn that the batch will be condemned under the slower tests. Immediate action on the part of the Company of Fishmongers, enables the requiremnts of the health authorities to be carried out without delay.

Abstracts from Current Literature

GASTROENTEROLOGY

X Rays in the Diagnosis of Organic Diseases of the Colon.—Arthur F. Hurst (*British Medical Journal*, May 23, 1925) states that in estimating the value of radiology in the diagnosis of organic diseases of the colon, it is necessary to compare it with the other available methods of confirming, or otherwise, suspicions aroused by consideration of the patient's history. Apart from the ordinary physical examination of the abdomen and digital examination of the rectum, the only direct means of investigating intestinal diseases are the x rays, investigation of the stools, and sigmoidoscopy.

An x ray examination after an opaque meal never reveals an obstruction of the colon which cannot be recognized with an opaque enema, but it is useful in the diagnosis of obstruction of the small intestines, especially near the end of the ileum. An opaque enema shows the presence of obstruction at a comparatively early stage, often long before localizing symptoms develop. But a negative result does not exclude a growth of the colon. An opaque enema is the only certain clinical means of recognizing diverticula of the colon. This is of great importance, as it may be impossible, even at an explanatory operation, to distinguish between a growth and an inflammatory mass secondary to diverticulitis. That ulcerative colitis may lead to stricture on healing has also been shown by x rays. In these cases, delayed recovery, whether an appendicostomy has been performed or not, is thus an additional indication for x ray examination.

Microscopical examination may show the presence of blood corpuscles and pus in stools which look normal to the naked eye. Much more frequently blood can be recognized by chemical means and by the discovery of hematoporphyrin or acid hematin with the spectroscope.

The sigmoidoscope is so invaluable in diagnosis that every practitioner should learn to use it himself in cases of supposed colitis or unexplained disturbance in the functions of the bowels. With its aid a growth of the upper part of the rectum or lower part of the pelvic colon can be recognized before it can be felt—often before a barium enema shows any definite abnormality.

Spread of Cancer of the Rectum.—As a result of 1, noting the position of metastases during the performance of operations; 2, observing the locality affected by recurrent growth either clinically or during the performance of secondary operations; 3, recording the extent and the position of metastases in cases in which proposed operations had been abandoned on account of their presence; 4, studying the postmortem findings in regard to the spread of cancer in patients who had died from advanced and inoperable cancer, and 5, following the detailed examinations, macroscopic and microscopic, of specimens removed by operation, W. Ernest Niles (*Lancet*, June 6, 1925) has been able definitely to determine the tissues that are liable to metastatic deposit during the progress of the disease and to recurrence after restricted operations. These tissues are the ischiorectal fat, the levatores ani muscles, the pelvic peritoneum, and the pelvic mesocolon, and they are directly concerned with the spread of cancer from the rectum. Pathology teaches us that they may be the seat of metastatic deposits even when the growth in the rectum is in a clinically early stage, and that unless these highly dangerous tissues are completely removed in every case in which an operation for the removal of the cancerous rectum is undertaken, postoperative recurrence will be the rule to which there will be few exceptions.

Diet that Puts the Gastric Ulcer Completely at Rest.—Alexander Jarotzky (*Schweizerische medizinische Wochenschrift* June 4, 1925) proposes a very simple diet for the treatment of gastric ulcer. After the onset of a severe hemorrhage or during it, the patient is kept in bed and is given the raw white of an egg in the morning and twenty grams of fresh unsalted butter at about 3 p. m. This is increased every succeeding day by one white of egg and twenty grams of butter, so that on the tenth day, about the whites of ten eggs and 180 grams of butter are given. Aside from this food, the patient is given nothing to eat or drink—no drugs and no nutritive enemas. This diet fails only in the cases of very marked obstructions (stenoses) in the region of the pylorus or that of the anastomotic opening. To apply this diet for longer than ten days would be to disturb him unnecessarily. After this period the patient is given egg albumen in the morning, and in the afternoon strained soups, which are made in water without salt and with fresh unsalted butter from various cereals (rice, manna, barley, etc.), then mashed potatoes and various purées of vegetables (also cooked in water, without salt, and with butter). Absolutely no milk is given during the whole treatment.

Intestinal Obstruction Due to Ascaris Lumbricoides.—Sidney H. Glass and Charles James Bloom (*Archives of Pediatrics*, September, 1925) report a case of intestinal obstruction due to Ascaris lumbricoides in a white boy of nine years and propose questions on the cause of the abrupt obstruction which resulted in the child's demise. During the seven days of treatment fifteen minims of carbon tetrachloride were administered the second day, and subsequently stimulants when the patient grew depressed and refused nourishment. The questions are: Was the obstruction influenced by carbon tetrachloride, codeine, alcohol, or toxins liberated from the dead worms? Then, too, if surgical intervention had been sought earlier, would the boy's life have been spared. The partial autopsy showed eight feet of the intestines to contain continuous masses of worms.

Colon Bacilli in the Digestive Tract, Especially in Connection with Pernicious Anemia.—Francesco Paolo Tinozzi (*Klinische Wochenschrift*, May 21, 1925) draws the following conclusions from his experimental studies on the subject:

1. Numerous bacteria, that are visible in the smear specimen but cannot be cultured, are found in the gastric juice of every individual.

2. The content of bacteria that can be cultured depends upon the total acidity and the content of free hydrochloric acid in the gastric juice. Studies on corpses do not show the same results.

3. There is no essential relationship between the hemolytic property and the virulence of the colon bacilli, inasmuch as there are strains showing very slight virulence among the markedly hemolytic strains.

4. In a patient afflicted with pernicious anemia and an artificial anus there was, along with the improvement in clinical symptoms, a diminution in the number of bacteria in the gastric and intestinal juices and an increased power of agglutination in the blood serum; with an aggravation of the condition, on the other hand, the reverse was found.

5. In this patient, the strains from the stomach showed a greater power of agglutination than those excreted along the fistulous tract.

6. The hemolytic strains show a greater power of agglutination than the nonhemolytic strains.

7. There is a reciprocal relationship between the agglutinating power and the virulence: the most virulent strains are also those showing the greatest power of agglutination.

Hemoclasic Crisis Test for Liver Function.—A. F. Bernard Shaw (*British Medical Journal*, May 16, 1925) finds that Widal's hemoclasic test for liver function lacks a theoretical basis, and in practice is of no value in the diagnosis of hepatic insufficiency. During physiological rest the number of leucocytes in the peripheral blood is subject to considerable and rapid fluctuations, though there are phases in which a state of equilibrium exists. There is no evidence that the ingestion of milk, casein, butter fat, and distilled water in certain quantities, or the local application of cold, influences the leucocytic content of the peripheral capillary blood, the oscillations following these stimuli being the same as the physiological variations during rest. The phenomena of "digestion leucocytosis" and "digestion leucopenia" described in connection with the hemoclasic test are simply physiological variations and not the response to ingestion of foodstuffs. The conflicting conclusions as to the value of the hemoclasic test arise from a failure to recognize that normally the leukocytic content is in a state of flux, and consequently that a single count made before the test does not represent a state of equilibrium.

Gastric and Duodenal Ulcer Variously Treated.—Theodore C. Greene (*Boston Medical and Surgical Journal*, June 18, 1925) has made a study of the results of medical and surgical treatment of gastric and duodenal ulcers at the Peter Bent Brigham Hospital, and gives this summary of the results: Complete relief, thirteen medical, ninety-three surgical; partial relief, eleven medical, seventeen surgical; no relief, eleven medical, six surgical; complications, four medical, one surgical, making a total of thirty-nine medical and one hundred and seventeen surgical.

Of one hundred and seventeen patients treated surgically and followed, 79.5 per cent. obtained complete relief, 14.5 per cent. obtained partial relief, 5.1 per cent. obtained no relief, and 0.9 per cent. suffered a hemorrhage. All those obtaining no relief underwent a second operation which was successful in all the cases, four in number, who replied to followup letters.

In two hundred and fifty-nine consecutive operations upon elective and uncomplicated cases of gastric and duodenal ulcers, there were five deaths, a mortality of 1.9 per cent.

The author points out that medical treatment is not without its dangers and finally says that in choosing between medical and surgical treatment, the intelligence and ability of the patient to cooperate must be considered, as well as the clinical aspect of the case.

Sporothrix Infection of the Large Intestine and Fingernails.—Thomas R. Boggs and Hiram Fried (*Bulletin of the Johns Hopkins Hospital*, September, 1925) report a case with clearcut dysenteric colitis, apparently due to a streptothrix infection, which is the first on record. The patient had had a gradual and painless thickening of the fingernails for years, and she had been in the habit of biting her fingernails. An acute and severe dysentery occurred, with from ten to twenty stools a day. From these an organism which in size and characteristics conformed generally to the Sporothricium schenckii was recovered in pure culture, although it is not certain that it belonged to this species. Effective treatment was finally instituted by the use of gentian violet given in capsules with a salol coating, which just allowed the color on the dye to show through, these passing the stomach without being dissolved, but staining the intestinal contents deep purple. Such pills were given every six hours, and almost immediately the organisms began to diminish in the stools, and after a week could no longer be recovered on culture nor demonstrated in microscopic examination.

Effect of Additions of Fluorine to the Diet of the Rat on the Quality of the Teeth.—E. V. McCollum, Nina Simmonds, and J. Ernestine Becker (*Journal of Biological Chemistry*, April, 1925) carried out experiments to determine whether, using certain diets, the addition of amounts of fluorine comparable to what might be expected to occur in natural foods would favorably influence the teeth in rats. The inclusion of 226 parts per million of this element in the form of sodium fluoride was tried. The results showed, contrary to expectations, that the ingestion of fluorine in amounts but little above those which have been reported to occur in natural foods markedly disturbed the structure of the teeth.

CARDIOVASCULAR DISORDERS

Functional Heart Disease in Children.—Mansfield G. Levy (*Archives of Pediatrics*, September, 1925) reports that he has found some instances of heart disease that might be mistaken as functional but were due to organic causes. In his experience not all the arrhythmias or irregularties of the heart, as heard by the stethoscope or felt at the pulse, are simple sinus arrhythmias. There are organic irregularities that may be explained by the presence of a myocarditis or a pericarditis; in fact if it were possible to autopsy cases of irregularity, many of them migh show evidence of a true myocarditis. Some of these irregularities, especially those associated with rheumatism, originate in a myocarditis that exists because of the presence of Aschoff bodies. Occasionally there are cases in which an abnormally slow heart action may be due to an infection associated with rheumatism, diphtheria, influenza, or other infection. A few isolated cases of heart-block in children in association with diphtheria have been reported.

Dr. Levy adds that simple systolic murmurs, heard most commonly over the pulmonic area, may or may not be functional.

Radium Emanation in Angina Pectoris.—J. Pelnar (*Presse médicale*, August 5, 1925) refers to encouraging results obtained by his assistant, Vanysek, with intravenous injections of radium emanation in disturbances of the vegetative nervous system, especially those which are favorably affected by periarterial sympathectomy—peripheral vasoconstrictions and trophic disorders of the distal portions of the extremities, typified by Raynaud's disease. The emanation usually moderates the irritability of the sympathetic, diminishing peripheral vasoconstriction, improving the blood supply of the affected member (as shown by oscillotonographic curves), hastening demarcation in necrotic processes and reducing pain. In some cases of obstinate angina, the emanation removed the need for the operation of sympathectomy. The procedure is particularly effective in angina pectoris with exclusively peripheral pain, where vasomotor phenomena are prominent and the pain is brought on by cold. The method is as follows: The emanation, obtained from the laboratory in a sealed ampoule, is quickly dissolved in a little physiological salt solution, distilled water added to make twenty mils, and the whole injected into a vein of the arm. A course consists of six injections, given at the rate of one to three a week. An interval of two or three weeks should then elapse before further injections are given. The dose of emanation injected is five to six millicuries. In vasomotor disturbance of a lower limb, the same favorable effects were obtained by hypodermic injections of emanation in the affected limb, in the vicinity of the lesion; for such injections the dose was only one-third millicurie, dissolved in five or six mils of water. The action of the emanation is mainly regional, even after intravenous injection; in angina it is therefore generally administered in the left basilic vein.

Low Blood Pressure in Angina Pectoris and Other Cardiac States.—V. Libensky (*Presse médicale*, August 5, 1925) observed low blood pressure in twenty per cent. and weak heart action on fluoroscopic examination in thirty-five per cent. of cases. The low pressure cases were nearly all among those showing weak heart beats. The low pressure anginal cases were found to respond poorly to treatment. The same peculiarity was noted in a special form of hypotension characterized by weak heart beats on fluoroscopic examination, normal dimensions of the heart, and normal general health. This condition was found frequently in persons practising sports to excess, in old persons indulging in active sports and in individuals undergoing forced weight reduction. The low pressure is for a long time compatible with a subjective feeling of complete health and a frequently superior degree of physical performance. Such hearts, however, are subject to sudden failure under varying stresses such as pregnancy and, in particular, chloroform anesthesia. In these patients digitalis tends to bring on arrhythmias such as alternating pulse, bigeminal pulse, complete arrhythmia with tachycardia, premature contractions, etc., as well as pulmonary embolism and in infarction. Disappointing results followed digitalis in all cases of this type, and the patients soon felt better when digitalis was stopped and replaced by theobromine and sometimes camphor and strychnine. The failure of digitalis in these cases recalled that seen in heart block. In some patients low pressure should serve as a warning against the use of digitalis, unless it be given with great caution.

Arteriotomy in Embolism of the Axillary Artery.—C. Lian and P. Mours (*Presse médicale*, September 23, 1925) report the case of a woman aged fifty-two years with high blood pressure and cardiac insufficiency in whom pain developed suddenly in the right forearm, with numbness and tingling of the hand and pallor of the entire limb. Next day no pulsations could be felt in the radial, brachial or axillary arteries, though weak pulsations were palpable at the apex of the axilla. Localized pain in the axilla led to the discovery therein of a hard, elongated body which was taken to be the artery occluded by a clot. The patient's acute exacerbation of heart weakness having already been dispelled by treatment, embolectomy under local anesthesia was undertaken. The local anesthetic employed was niketol—chemically described as ethyl paraminobenzophthalamate hydrochloride. Through a twelve centimetre incision the distal portion of the axillary was found slightly dilated, grayish and indurated. A clamp having been placed below on the brachial artery, an incision twelve millimetres long was made in the axillary along the lower portion of the occluded seg-

ment, and a dark clot twenty-five millimetres long driven out in several sections by gentle expression of the vessel. Blood spurting actively soon after, the vessel was clamped above and the operative field covered with liquid petrolatum a d compresses soaked in it, except for the segment of artery between the two clamps, in order to prevent contact of the sutures with the raw surfaces and absorption of tissue fluids by these sutures. The incision in the artery was then sutured with linen thread, the outer vascular layer of the vessel sutured with catgut, the area washed with ether to remove the petrolatum, and the wound closed. The results of the operation were completely successful, circulation and blood pressure in the affected extremity soon equalling those on the opposite side, and continuing normal. Arteriotomy for embolism deserves to be a routine procedure in cases exhibiting indications for it. General anesthesia should never be used. Embolism may be distinguished from thrombosis through the fact, pointed out by Cassaet, that above an embolism the arterial pulsations are generally of greater amplitude than those in the corresponding region on the opposite side. Spontaneous restoration of circulation in a limb following embolism is a possibility, but one should avoid delaying operation until permanent lesions of the arterial wall have been produced or an extensive clot has formed. Such a clot, by blocking the collateral vessels, prevents the later return of circulation. The writers would prefer to operate to remove the clot and then simply ligate the artery if suture is not feasible, rather than not to operate and thus allow a long clot to form and compromise the collateral circulation.

Influence of High Blood Pressure in Cataract Surgery. Frank E. Burch (*Northwest Medicine,* January, 1925) points out that abnormal arterial hypertension occurs in approximately forty per cent. of cataract cases and may not be disregarded in consideration of the operative risk. Danger of complication at operation and during convalescence is relatively slight when ordinary precautions are instituted. These precautions are definitely indicated by the sphygmomanometer and consist in the main of preliminary rest in bed, laxatives to relieve splanchnic engorgement, sedatives, restricted salt free diet and perhaps in extreme cases venesection. Very high blood pressure and its associated circulatory conditions are important causes of hemorrhage. The frequency with which high blood pressure is found associated with failures due to iridiocyclitis and chronic uveitis would indicate that the same underlying causes were factors in producing these two conditions.

The Influence of Experimental Atherosclerosis Upon the Systolic Blood Pressure in Rabbits.—Shepard Shapiro and David P. Seecof (*Journal of Laboratory and Clinical Medicine,* July, 1925) using Anderson's method, studied the systolic blood pressures of seven rabbits which were being fed lanolin for the production of atherosclerosis, and of a number of control rabbits kept under similar hygienic and dietary conditions. These observations failed to confirm the conclusions of Fahr, Van Leersum, Schmidtmann and Schönheimer that feeding rabbits with cholesterol containing substances over long periods of time causes elevation in blood pressure. These observations on blood pressure during the development of atherosclerosis in rabbits suggest that increase in blood pressure is not an essential factor in the deposition of lipoids in the intima.

Value of Venesection in the Treatment of the Decompensated Heart.—Burgess Gordon (*American Journal of Medical Sciences,* November, 1925) says that the röntgenographic examination of a series of decompensated hearts in patients with failing circulation showed a diminution in the size of the heart immediately after venesection. When this occurred, there was a corresponding improvement in the condition of the patient. It is suggested that the hearts in these cases are more efficient in a moderately dilated form than when extremely dilated. In those cases where no changes in the heart size occurred, it is felt that the muscle tone was so unresponsive to venesection because of certain anatomical changes in the myocardium that no improvement occurred in the circulation. A survey of the hospital records shows that numerous patients, bled as an emergency measure after other procedures of therapy such as drugs had failed possibly because of their delayed action, responded favorably to venesection. It seems, therefore, that venesection has a place in improving the action of the decompensated heart and temporarily at least in removing signs and symptoms of failure.

The Heart in Chronic Toxemia.—H. Clulow Nixon (*British Medical Journal,* April 11, 1925) reports that there appears to be a definite connection between leftsided preponderance and a hypertonic state of the arterial wall. When by treatment the toxins are removed, and can no longer act as irritants to the wall of the artery, leftsided preponderance disappears. Coincidently the T-wave negativity in lead III in the electrocardiogram depends on the cardiac atony, and it tends to assume its normal deflection as the toxemia becomes less pronounced, the heart regaining its power of sustained partial contraction, in which stretching is resisted. From the foregoing it would seem that the generally accepted view that inversion of T in lead III when it appears is a normal even is incorrect.

The heart responds quickly to treatment directed to the removal of the focal infection and to eliminative methods, such as are carried out in spa treatment, even though the poisoning has been of long duration. The importance of adequate treatment to the alimentary canal, particularly intestinal, cannot be overestimated.

Coronary Sclerosis.—Since there is no generally accepted conception of the clinical significance of coronary sclerosis, M. H. Nathanson (*American Journal of the Medical Sciences,* August, 1925) has constructed a clinical picture by an analysis of a series of fatal cases which came to necropsy. The following points are brought out:

1. Coronary sclerosis is most common in males and in the age period between fifty and seventy years.

2. The outstanding clinical feature is the presence of attacks, usually of pain, less frequently of acute respiratory distress. The pain is most often in the chest, but abdominal attacks are not uncommon.

3. These attacks occur with either of the following combinations: Normal sized heart, with no evidence of cardiac failure, 37.2 per cent.; normal sized heart, cardiac failure present, 26 per cent.; cardiac enlargement, congestive failure absent, 22.6 per cent.; cardiac enlargement, congestive failure present, 38 per cent.

4. The clinical features of coronary thrombosis are essentially similar to those of coronary sclerosis; thrombosis, therefore, should not be considered as a clinical entity but merely as a complication of coronary sclerosis.

5. The outstanding pathological features are the following: Changes in the coronary arteries are most marked in the left branch. In addition to coronary sclerosis, thrombosis occurs in approximately one fifth of the cases. Myocardial involvement paralleling the degree of coronary sclerosis is a constant finding. Lesions in the aorta of any significance are present in but a small percentage.

Indications for the Use of Quinidine Sulphate in Heart Disorders.—Paul D. White and Howard B. Sprague (*Boston Medical and Surgical Journal,* July 16, 1925) say that quinidine sulphate is often helpful in preventing paroxysmal auriculur fibrillation, no matter what the condition of the heart, when given in daily rations of about three or six grains in tablet or capsule form once or twice a day, or two grains two or three times a day. Patients, who are generally sensitive nervously, who have obtained relief in whole or in part from the disagreeable paroxysms of fibrillation by the use of quinidine sulphate are grateful.

Sometimes the drug is also helpful in preventing paroxysms of regular auricular tachycardia. In about half of the cases in which we have so used it there has been distinct relief, but it is less effective than in paroxysmal auricular fibrillation. In getting rid of extrasystoles or premature beats it has been ineffective in the few cases to whom we have given it.

Finally quinidine sulphate may be of much value in restoring normal rhythm in cases of recently established permanent auricular fibrillation, or of prolonged paroxysmal auricular fibrillation, in whom there is no history of congestive failure, no extensive heart disease—valvular (mitral stenosis, etc.)—or otherwise, and no sensitiveness to the drug. After it has been ascertained by a small dose (two or three grains) that the individual is not easily poisoned by the drug—and such poisoning is rare—it can be given in fairly large doses by mouth for several days without danger, provided the patient remains quiet and under close observation, so that the heart may be examined for normal rhythm or abnormal tachycardia, and toxic symptoms observed, on each occasion before the next dose is due. The toxic symptoms are those of cinchonism. The dose that we have found most

effective is six grains for five doses at two hour intervals daily until normal rhythm has appeared, toxic symptoms or signs developed, or the treatment continued without effect for a week. Although ambulatory cases may be so treated it is safer to give the drug in these large doses under close observation.

The restoration of normal rhythm in these cases of chronic auricular fibrillation may not only relieve the patient of very disagreeable palpitation, but also enable him to be physically more efficient, partly because of the relief of the symptoms and partly because his circulation is improved. In no sense of course is quinidine sulphate to be used in the treatment of congestive failure or angina pectoris—it is not intended to replace digitalis or the nitrites.

SURGERY

Contributions to the Surgery of Abdominal Hernia.—Weller Van Hook (*Boston Medical and Surgical Journal,* October 15, 1925) recommends to expert surgeons, not to amateurs, the following procedures. 1. When the patient has a "pot belly," or, whether fat or lean, has greatly relaxed abdominal walls, an operation called by him laparoplasty. On each side of the abdomen, low down, a flap is raised, pedicle above, involving the outer musculature with the attendant aponeurotic tissues. The raised masses are not unlike the lower corners of the flaps of a man's unbuttoned vest. These flaps are to be sutured back again, but with maximal overlapping. The effect is striking. The lower abdomen is "tucked in" and the inguinal regions are protected. These effects should be produced pronouncedly, but not excessively. This laparoplasty will be found a useful adjuvant in the management of abdomens subject to hernias. 2. Transplantation of the lower part of the rectus muscle or muscles to a new attachment, or to new attachments, namely to Poupart's ligament, or to the ramus or rami of the pubic bone or bones. A part of the rectus muscle, together with a great section of the anterior layer of its sheath, is lifted, except for its pedicle above, and shifted over to be attached to Poupart or to the pubic ramus. With the use of the spinal flexion already emphasized the transplantation leaves no tightness to interfere with healing and the defect made can be closed with lateral sutures or covered by free fascia lata grafts. The support given to the weak part of the abdomen is great; especially do we thus find a useful supporting buttress. The pubic bone can be drilled to provide supports for sutures, but, thus far, I have not been obliged to do more than stitch to the powerful connective tissue masses usually found attached to the bone. Poupart's ligament should be used only in the less serious cases because it is not strong enough to meet very heavy demands.

3. The external oblique muscle and its aponeurosis together with the internal oblique may be taken up as a flap by incisions at their attachment to the rectus sheath and just within the inner wall of the inguinal canal. This flap, somewhat different from that used in my laparoplasty, may be carried down to overlap and immediately to fortify the canal, especially at its lower extremity, which is often weak. This flap when carried down is also rotated a little.

4. In suitable cases, the application of powerful sutures of chromicized catgut or of connective tissue taken from the patient's own body to grasp or even to surround weak parts of the abdominal wall. The typical example of this method is that of surrounding the inguinal canal with deeply placed sutures.

By running the gloved finger along Poupart's ligament when the inguinal canal is opened that band may be readily outlined and sutures may be carried around it, and on the inner side may be passed around a great part of the costosternopubic musculature. Such sutures give a far greater security than small sutures placed from within the canal.

5. Fascial sutures are of the utmost importance in the surgery of the abdominal wall. For this purpose he has used and recommends powerful free ribbon grafts of fascia lata, of aponeurosis, or, when available, bands cut from the hernia sac. These bands from the fascia lata should be from a quarter to three quarters of an inch wide and from three to eight inches long. The external oblique aponeurosis yields usually one good graft without interference with its closure. These great transplants applied about the inguinal canal and the neighboring musculature are most useful because they are strong, aseptic, and "biologically suited" to their new environment.

Tonsillectomy by Propulsion and Avulsion.—J. Bowring Horgan (*Practitioner,* August, 1925) thus describes how he performs this operation:

"I operate with the patient in the dorsal recumbent position, the head being unsupported, and the whole body well to the right hand side of the table, on which side I stand. It is important that the table should be low in relation to the stature of the operator. I only use two instruments, a Doyen's gag, and a medium sized Jenkins' modification of the Ballenger type of reversed action tonsillectome. It is important that the blade of this instrument should be so blunt that it would, in action, be powerless to sever by manual pressure the bunched up tissues which it encircles. As obtained from the instrument makers, the instrument is invariably too sharp, and its blade should be reduced to the approximate bluntness detailed above.

In order to achieve a total enucleation in all cases, it is necessary to make sure that the blade of the tonsillectome is of the requisite bluntness, that this blade cuts well home on to a leaded groove, that one obtains a massive, but not necessarily an extracapsular hold of the tonsil, and that the latter is finally avulsed from its bed and not cut from it.

"I use the forefinger of the disengaged hand to depress the tongue and bring the tonsil into view. The ring of the instrument having encircled the tonsil, the latter is lifted forwards above the alveolar eminence of the lower jaw, the thumb or forefinger of the disengaged hand being used to apply counterpressure through the anterior faucial pillar. At the termination of this movement, and before the blade is made to close, the shaft of the instrument should lie obliquely across the patient's mouth, making an angle of about 45° with the horizontal, in which position its handle should come to lie about the level of the patient's opposite shoulder. A firm hold of the tonsil having been obtained and retained, the final or avulsive movement is initiated as soon as the handle of the instrument has been brought back to its primary position. It is a remarkable fact that the tonsil so held and pulled upon will almost invariably peel cleanly from its bed and not break away. The avulsion is best carried out by a series of very sharp tugs during which the operator's two hands are locked around the handle of the instrument. A great and seemingly alarming amount of traction is often requisite to attain the end in view. The anesthetist, who stands at the head of the table, must be advised, of this maneuvre, so that he may exert steady counterpressure with both hands which, in this manner, retain the head in its horizontal position.

Ambidexterity in the use of the instrument is essential to the rapidity of action which is desirable. Though I use reflected light, I rely rather on my tactile sense than upon my vision in the proper apposition of the instrument and the digital propulsion of the tonsil within its ring. Facility in these two matters is important if the obvious dangers of delay and the use of throat swabs are to be avoided.

Effect of Operative Interference with the Cervical Sympathetic Nervous System Upon the Growth and Malignancy of a Transplantable Neoplasm of the Rabbit.—Louise Pearce and Chester M. Van Allen (*Journal of Experimental Medicine,* October, 1925) studied the effect of the removal of the complete cervical sympathetic nervous system, of both superior and of both inferior cervical ganglia, and of a small portion of the cervical sympathetic nerve in the rabbit in relation to the character of a malignant disease induced by a transplantable neoplasm. The general character of the disease developing in the operated groups was more severe than in a control group, as shown by comparisons of the mortality rate, of the animal incidence or metastases, the number of metastatic foci, and the distribution of these secondary growths. There was apparently, however, a difference in malignancy among the operated groups themselves. The most severe disease occurred in the group where a portion of the sympathetic nerve only was removed (sympathotomy); that in the complete sympathectomy and superior sympathectomy groups was slightly less malignant; and that in the inferior group was much less so. The results are interpreted as due to a less effective animal resistance, the mechanism of which has been interfered with in some way by the interference with the sympathetic nerves. A tentative explanation for the reasons for the difference in malignancy in the several groups is suggested upon the basis of coordinating, favorable or deleterious functions subserved by the cervical sympathetic nervous system.

CONTRACT BETWEEN CITY AND HOSPITAL FOR TREATMENT OF POOR HELD TO REQUIRE COMPETITIVE BIDDING

The Kentucky Court of Appeals holds, Mosely Hospital v. Hall, 269 S. W. 1004, that a two year contract by a municipality of the third class with a hospital for care and treatment of the municipality's poor came within Ky. St. §3440, requiring advertisement for bids for a contract for work or supplies over $500. It is held immaterial that there are but two hospitals in the city, and both made application for the contract. There was no advertisement for bids and no specification of requirements or any other standard fixed by ordinance or resolution by which any contract could be submitted to competitive bidding. The contract being let without advertisement could not be declared legal because the city suffered no disadvantage by reason of the illegal manner in which it was executed.

INSURED PERSON'S FALSE REPRESENTATIONS AS TO HIS HEALTH

The Texas Court of Civil Appeals holds, Judd v. Lubbock Mut. Aid Assn., 269 S. W. 284, that where the insured is the beneficiary, and the insurer's agent, who was a kinsman of insured and the beneficiary, knew of the insured's bad health, his false representation in his application that he was in good health constituted a warrant, and the insurer was not bound by the certificate issued thereon.

WHETHER SUBSTITUTE PRACTITIONER AGENT OF FIRST HELD QUESTION FOR JURY—DOCTOR NOT OBLIGED TO USE "ALL KNOWN AND REASONABLE MEANS" TO EFFECT A CURE

In an action for damages alleged to be caused by the defendant physician and surgeon's negligence in failing properly to care for plaintiff after an operation affecting her left knee, where the evidence conflicted on the main issue as to whether the plaintiff received proper care and attention from defendant under the circumstances, the North Carolina Supreme Court held, Nash V. Royster, 189 N. C., 408, 127 S. E. 356, that the question was one for the jury. As to whether another doctor was the defendant's agent in looking after the plaintiff's case during the defendant's absence was also held to be a question of fact for the jury. Whether an agency in fact had been created was to be determined by the relations actually existing between the parties under their agreements or acts, and was not influenced by the knowledge or consent, or lack of such, of the plaintiff. Evidence of custom among local physicians was held competent as bearing on the question of agency. It was held error to charge as matter of law, that the relation of principal and agent necessarily existed by putting the patient in the charge of another doctor without the consent of the patient or her parents.

"By the clear weight of authority," the court said, "a physician or surgeon who sends a substitute practitioner to treat a case, on becoming unable personally to fill a professional engagement, is not liable for the latter's negligence or malpractice, unless the substitute acts as his agent in performing the service, or due care is not exercised in selecting the substitute practitioner. . . .

"A physician or surgeon is not bound to render professional services to every one who applies, and he may therefore, by notice or special agreement, limit the extent and scope of his employment. . . .

"But when a physician or surgeon takes charge of a case and is employed to attend a patient, unless the terms of employment otherwise limit the service, or notice be given that he will not undertake, or cannot afford, the subsequent treatment, his employment, as well as the relation of physician and patient, continues until ended by the mutual consent of the parties, or revoked by the dismissal of the physician or surgeon, or until his services are no longer needed. And he must exercise, at his peril, reasonable care and judgment in determining when his attendance may properly and safely be discontinued.

"As a general rule, in the absence of any special agreement limiting the service, or reasonable notice to the patient, when a surgeon is employed to perform an operation, he must not only use reasonable and ordinary care, skill and diligence in its performance, but in the subsequent treatment of the case he must also give, or see that the patient is given, such attention as the necessity of the case requires.

"But the law does not require of a physician or surgeon absolute accuracy, either in his practice or in his judgment. It does not hold him to a standard of infallibility, nor does it require of him that utmost degree of skill and learning known only to a few in the profession. He is not answerable for mere errors of judgment, where good judgments my differ. . . . Liability may attach for errors of judgment, however, where they are so gross as to be inconsistent with that degree of skill and competence which it is the duty of every physician or surgeon to employ in the treatment of a case."

An instruction was held erroneous which charged that "there is an implied contract that the physician will use all known and reasonable means to accomplish the object for which he is called to treat the patient." A physician or surgeon is not required to use "all known and reasonable means" to accomplish the object for which he is employed, unless by specific contract he obligates himself to do so. For errors in charging the jury, judgment for plaintiff was reversed.

CAUSE OF ACTION FOR PERSONAL INJURY CANNOT BE JOINED WITH CAUSE OF ACTION AGAINST PHYSICIAN AND SURGEON FOR MALPRACTICE

The New York Court of Appeals holds, Ader v. Blau, 241 N. Y. 7, 148 N. E. 771, that two independent causes of action, one of which alleges that the death of plaintiff's intestate was caused solely by the negligence of one defendant in erecting and maintaining an iron picket fence whereby intestate was injured in a manner causing infection and death, and the other alleges that the intestate came to the other defendant as a physician and surgeon for treatment, and that the latter so negligently treated him that, solely by reason of such negligent treatment, intestate died, cannot, under New York Civil Practice Act, sections 209, 211, 212, 258, be united in one complaint, the causes of action not being consistent and not arising out of transaction connected with the same subject of action.

STATUTORY PROVISION FOR SUPPRESSION OF RABIES

Reversing a conviction for obstructing a health officer by refusing to surrender, to be tested for rabies, a coyote which had bitten a man, the Oklahoma Criminal Court of Appeals holds, Shilkett v. State, 232 Pac. 127, that within reasonable bounds the Legislature may confer regulative powers upon the state board of health and give to that board authority to adopt rules and regulations having the force and effect of law; but where the public health statutes make no specific provision for the suppression or control of rabies and there are no averments in the information that the state board of health promulgated any rules on that subject, the courts will not assume that such rules were promulgated.

The Influence of Oral Sepsis in the Production of Disease

F. G. CROOKSHANK, M.D.LOND., F.R.C.P.

London

I

In this brief discussion of the part played by oral sepsis in the production of disease, it is proposed to consider only those forms or states of oral sepsis that pertain to the province of the dental surgeon. For, not every form of oral sepsis is dental in origin, nor even in its relations.

Thus, various acute and chronic septic mouth states arise in consequence of sundry specific and nonspecific infections quite apart from dental implication, as also in the course of acute and chronic maladies of general interest.

Again, although dental and gingival sepsis frequently precede the establishment of septic states in the nose, and its accessory passages and chambers, the inverse relation is not uncommon. Nasal sepsis, by inducing mouth breathing, and so altering mouth conditions, may bring about dental and gingival sepsis. Watson-Williams, indeed, has suggested that an even closer link may obtain between primary nasal and secondary dental sepsis (1).

But the interest to the physician of oral sepsis that is primarily dental or gingival by far transcends that of other forms of oral sepsis. By reason of its intractability, and of its persistent and generally progressive character, it is extraordinarily liable to provoke infections of all kinds, and degenerative conditions generally in remote or adjacent organs, or affecting the whole system. However, it is only lately that the relations between oral sepsis and other forms of disease have been discussed at all comprehensively, while, even now, opinion is divergent, debate confused, and knowledge imperfect.

Two questions in particular are often propounded. First: How do we *know* that dental sepsis is causally related to other forms of disease? Secondly: How is it, if there be such causal relation, that difference of opinion should still exist, between and among doctors and dentists, as to its extent and the part it should play in determining treatment? (2).

A third question may be added: If dental sepsis be the frequent cause of other disease that it is said to be, how is it that so much oral sepsis is found in the mouths of persons of primitive race, and of so many seemingly healthy people among us, with so little sign of consequentially impaired health?

These questions are important, and call for answer. But the answering requires consideration of some general principles which, though frequently neglected, are yet indispensable to clear thinking in matters of pathology. The most confused notions prevail, for example, as to the nature of *a* disease, and as to what is implied when we speak of *a* cause, or of *the* cause of a particular *disease*. We say, too, that we know certain general statements to be true: but few reflect on our justification for the assertion.

Disease, or disorder of health, as we conceive it to be present in the persons who consult us, is made known to us by signs, which we speak of as symptoms, as physical signs, and the like. Experience teaches us, that in each case the appearance of these signs of disease is related to a whole group of precedent conditions that we recognize as *causes* of the disease.

This recognition of causal relation is nothing more or less than the recognition, in experience, of constant or frequent association in sequence. No one has the faintest idea of the nature of the *action* that any *cause* is supposed to *exert* on the *effect* with which, in our experience, it is linked. In respect of any particular case, all the causes concerned are equally important in principle, but, when we find that, in respect of a group of like cases, one or more causes are common to every member of that group, we come to attach the greater importance to those causes, and to speak of them as *the* causes of that kind of illness.

Now the special, separate, and definite *diseases* described in our textbooks, as Sir Clifford Allbutt said so often and so justly, are not objective single things.

They are abstract, conventionalized, and formal concepts by means of which we conveniently summarize, memorize, and discuss our experiences concerning like groups of signs—symptoms, physical signs, and morbid appearances—in persons who are ill.

The special causes allotted in the textbooks to the special diseases therein described, represent those causes or associated antecedents most commonly or *necessarily* found in the like cases generalized in the description of the disease.

It is very necessary that the student should always bear in mind the distinction between particular cases

Copyright, 1926, by A. R. Elliott Publishing Company.

in patients, and the abstract generalizations we speak of as diseases. Descriptions of the latter, and of their causes have not the enduring value that we can attach to descriptions of perceptual single objects, like coins or postage stamps; they are subject to revision, to rearrangement, and even to rejection as our experiences increase and our convenience demands. At the present time medicine is passing through a period in which many of our notions concerning the causation of disease in general and diseases in particular are being reconsidered.

In a formal and perfectly correct way we consider the tubercle bacillus (more correctly *infection* by the tubercle bacillus) to be *the* cause of the disease we call tuberculosis. That is to say, infection by the bacillus, if achieved, produces all the signs by which as we say the disease is known, and, no case in which all these signs are present is without infection by this kind of bacillus. But, when I consider the case of any particular patient—let me say that of the ex-service man who consulted me yesterday—I have to recognize that, for him, causes have been operative that may not be operative in every like, or nearly alike, case, but yet which have been *for him* of supreme importance. I have to decide, *for him,* what has been the causal relation of war service to the tuberculosis. But I have already decided that the precedent and obvious oral sepsis has certainly been a cause. Why? Because in my immediate (or personal) experience, as well as in the immediate experience available to me, this particular kind of case, with this history, and these signs, is so frequently associated with antecedent and continued oral sepsis of this kind that I am beginning to recognize, and even anticipate the association. So, too, my experience, and that of others, does not lead me to recognize any striking association between such war service as this man gave, comfortably ensconced in a billet at Boulogne, and the kind of bronchitic phthisis with dyspepsia, and scanty tubercle bacilli in the sputum, from which he is now suffering five years later.

It is true that, in the textbooks, infection by the tubercle bacillus is given as *the* cause of tuberculosis, or phthisis, and oral sepsis is not. Nevertheless, I am convinced that *in this case* I am right. But why? Because, though most or all of us do some time or another inhale or ingest many tubercle bacilli, only few of us suffer *infection* therewith. If those who do suffer actual infection are put in a group by themselves we find a certain number of antecedent conditions to have been common to many of them. And, by experience we come to correlate certain of these antecedent conditions with certain *types* of cases and so on. We go on then to determine causes for the subgroups, with a certain amount of crossreferencing, it is true, and ultimately learn to appreciate, as is said, the causal importance of many factors besides the textbook cause—infection by the bacillus, that is common to *all* the cases of tuberculosis.

Now oral sepsis is not a factor which, like infection by the tubercle bacillus, is always present in every case of a certain disease. And, the mere presence of oral sepsis, like the mere inhalation of the tubercle bacillus, does not necessarily involve consequent disease. But, although we admit that some persons may carry the products of oral sepsis, and the organisms of oral sepsis, as others carry the meningococcus, or Klebs-Löffler bacillus, without necessarily becoming the victim of consequent disease, we are nevertheless justified by experience and reason in making the general statement that it is frequently the cause of the most diverse kinds of ill health and disease, and in estimating its importance *in particular cases,* in accordance with what is known concerning like cases. If these notions are kept before the mind, the student will be saved the error of thinking that causes are things to be recognized as such in nature and in the laboratory, and will not need to trouble about the confusing distinctions sometimes made about predisposing causes, efficient causes, real causes, *causæ causantes,* and the like, all of which distinctions are artificial and have no direct relation with what actually happens in the clinical field.

Causation is the name we give to that kind of association in time and space between two events which experience leads us to expect, and recognize as necessary. The touchstone is experience of *what happens and is observed,* in the consulting room, in the laboratory and in the postmortem room.

A disease is the name we give to a group of symptoms, and the signs, clinical and pathological, that we associate mentally by reason of their recurrence in particular cases.

The cause of any particular disease is that cause, associated with that group of symptoms, etc., which, associated most frequently, or invariably with it, helps us best to define and delimit the disease.

The fact that oral sepsis is not associated, in this defining way, with any particular disease need in no way hamper us in recognizing its supreme importance in respect of very many cases, of very many diseases.

Now the evidence in favor of the importance of oral sepsis in relation to further disease is partly clinical, partly bacteriological and partly pathological.

Clinically we find that, in respect of certain groups of cases—of dyspepsia, of colitis, of arthritis and the like—that it is the only, or the most striking, common antecedent and factor.

Again, clinically, we find that striking alleviation often follows treatment of the oral sepsis in these kinds of cases, and we find, too, that treatment by drugs or surgery often fails unless the oral sepsis is actively treated as well. Finally, we find that, when treatment of the oral sepsis fails (though it is thought to have been a causal factor), perhaps permanent damage has been done, a blood infection has occurred, or some coincident cause of disease is persisting.

We find, too, that experience teaches us that septic conditions elsewhere than in the mouth are connected with the kind of consequences we are led to correlate with oral sepsis; we can find nothing in our experience of sepsis elsewhere than in the mouth to make us distrust the generalizations we make when we connote the experience of dentists and of doctors in respect of oral sepsis and associated disease.

We may go further. We sometimes notice a correlation between a "flareup" in the mouth, and the appearance of systemic disturbance.

We find that, of two persons—the one with a clean and the other with a septic mouth—though both be exposed to a sudden chill, or lowering influence, it is he whose mouth is unclean who suffers from acute illness. And so on. Such sets of circumstances can

be studied every day. But, because to many the idea of the correlation between oral sepsis and general disease is unfamiliar or distasteful *the clinical observation is not made.*

The bacteriological evidence is important, but is less decisive than the clinical. However, when a patient has a known gingival infection, and later becomes the subject of a blood infection by the same kind of organism, there is little room for incredulity.

The pathologist, or morbid anatomist, brings corroborative evidence into court. He finds the pathological lesions of the gums, of the bones, and of the lymphatics, to be similar to those found elsewhere in septic foci, and in relation to other disease. He finds no difficulty in telling the clinician that the connection he infers between oral sepsis and disease elsewhere is not in opposition to any principle of pathology, but in accord with all.

The whole weight of evidence, then, is in favor of recognizing, *in principle,* the great importance of oral sepsis in the production of disease. What is necessary now is to define the extent of its influence and the conditions of its exercise.

Again, two questions may be propounded. First: Why is it that in some persons oral sepsis should be relatively harmless and yet, in others, so noxious? Secondly: Why is it that oral sepsis should appear to be, to the one and same person, for long a matter of indifference, and yet suddenly to acquire importance?

The answers are not difficult to find, and are obviously interwoven. But we must beware of merely verbal explanations; of following Molière's physician who explained the soporific action of opium by alleging that the drug contains a dormitive principle.

In the course of a debate (Medical Society of London, December 11, 1922) three factors were spoken of as influencing the general effect of oral sepsis: to wit, the virulence of the organism, the amount of toxin absorbed, and the resistance of the patient. To speak thus is a convenient way of suggesting modes of difference, but we have no actual, or quantitative knowledge of this virulence, this toxin, and this resistance. But we may draw some analogy with what occurs in other pathological fields. We recognize, in the laboratory, that the poisons of some organisms are more virulent than others, and that these poisons become intensified or attenuated by culture. It is therefore not unlikely that when cultural conditions in the mouth change, the toxins produced (which are perhaps as much the result of tissue reaction to organismal growth as secretions by the organism) also change. And of course, new infections may occur.

We may recognize, too, that certain persons appear during life particularly unaffected by toxic and infective agents that are injurious to others, as also that some persons appear more liable, at certain times, to certain forms of malady than at others. We know that biochemical peculiarities sometimes, and what the French call physiological tissue inferiority at others, is suggested as explanatory of these apparent variations and differences in susceptibility. So it may be conveniently said that variations, 1, in *soil* conditions and 2, in *seed* conditions affect the resulting outcome.

The special circumstances of attack and defence must be constantly changing, in accord with internal and external adjustments in whatever terms of virulence, toxin formation, resistance, and the like we find it convenient to summarize what happens.

One word of caution is however necessary. Even though a particular patient may not be conscious of ill health, it is difficult ever to affirm that no slow degenerative process is, in any organ, developing in consequence of the disease process in the mouth. And it can never be affirmed that he who has a septic mouth is in so good trim, as he who has not, to escape the consequences of an accidental exposure to some specific organism or the complications that attend the ordinary acute infectious maladies that are accompanied by nasal, pharyngeal, respiratory and gastrointestinal catarrh. Experience during the late epidemic of influenza convinced me that fatal penumonia occurred with greater frequency amongst those with septic mouths (even when the patients were young and healthy) than amongst those with clean mouths.

On the other hand, we must admit that sometimes the prognostications of both doctor and dentist, in respect of a sick patient with a dirty mouth who refuses treatment, are, in the upshot, apparently unjustified. We may then, of course, say that the patient succeeded in establishing immunity!

But, the practical bearing of this discussion, which may be deemed abstract, is this: the relation to be assumed in any particular case between a state of oral sepsis and of further disease, whilst indicated by the presumption that disease in one part is prejudicial to health in other parts and in the organism as a whole, must be determined, not by the application of any dogma, but by the result of full examination and discussion, by both doctor and dentist, in the light of clinical experience, and in full appreciation of what justice there may be in the possibly opposed views of both.

Treatment depends, in every case, on the relation, spoken of above, that is assumed. The need for careful deliberation is then obvious.

II

But now to discuss the subject in greater detail, and from the point of view, not only of the dental surgeon, but of the bacteriologist, the pathologist and the general physician. Broadly speaking, the dental surgeon, when referring to oral sepsis, has in mind a series of processes or states that may usefully be set out in somewhat formal fashion, as follows:

1. Dental caries
2. Inflammations and infections of the dental pulp
3. Periapical infections, and dental cysts
4. Periodontitis
   - i. Cervical: acute and chronic.
   - ii. Gingival: chronic and acute.
   - iii. General: acute and chronic.

The discussion of the pathology of these conditions, and their distinction, the one from the other, forms no part of the purpose or scope of this paper; nevertheless, it is convenient here to recognize that these dental states fall conveniently into two groups:

1. Septic processes commencing at the gingival margin.

2. Septic processes involving, or culminating in periapical infections.

This grouping of the dental conditions is one that it is important to remember when discussing the subject as it interests the physician.

A bacteriological survey of the position gives us, as it were, a kind of cross reference to the dental classification.

TYPES OF DENTAL SEPSIS

We then recognize three main types—it might almost be said, stages—of dental sepsis.

1. In the first type, or stage, there is obvious disturbance of the normal relations between the ordinary flora of the mouth and the gingival and dental tissues, with proliferation of the common organisms of caries and of fermentation, or putrefaction. Thus, in addition to the ordinary mouth organisms there is an abundance of acid forming and liquefying microbes, among which are found staphylococci, sarcinæ, Bacillus subtilis, Bacillus liquor fluorescens and Bacillus proteus.

2. In the next type, or order, there is the presence of organisms which, though not specific in their effects are yet pathogenic and, in the main, pyogenic. Amongst these are Staphylococcus pyogenes longus, Streptococcus hemolyticus, Micrococcus catarrhalis, and Bacillus coli communis.

3. In the third type we find the added presence of organisms that are definitely associated with what are called specific forms of disease, and are given special names. Amongst these are the pathogenic amebæ, the pathogenic streptothrices (including actinomyces) the Klebs-Löffler bacillus, the tubercle bacillus, Vincent's spironema and the fusiform bacillus.

Thus regarded, the bacteriological situations of oral sepsis remind us irresistibly of what Mégnin has written in *La Faune des Cadavres*. Here an account is given of the successive squads of the workers of death—each squad with its allotted task—that attack, in regular order, the corpse exposed to the air. The analogy must not be pressed too far; the arrangement just suggested is tentative only; but we can still see that the notion of, as it were, accidental and irrelevant infection may have to give place to a conception of a succession of squads of workers of oral sepsis, attacking in order the tissues lowered by debility, or injured by neglect. This notion of workers in squads, too, helps us to realize how it is that specific infections may be truly said to be caused by antecedent and nonspecific infections, and carries with it a practical lesson too obvious to require statement.

To revert, however, for a moment to the grouping of the processes of dental sepsis, as seen by the dental surgeon, it is obvious that, from the point of view of the pathologist, the consequences of oral sepsis depend, not merely upon the bacteriological quality of the sepsis but on the situation of the septic foci.

When, with a gingival periodontitis, there is free discharge into the mouth, the pathological consequences will differ from what occurs when we have to deal with a periapical infection limited perhaps by a reactive osteitis. Stated roughly, from the physician's point of view, the end results of a caries that infects the pulp and leads to periapical reaction are quite other than those of a gingival periodontitis with free discharge, and a granulation barrier in the gum.

It is clear that, when we have to do with "open" sepsis, freely draining into the mouth, there will be surface spread of irritation and inflammation, followed by, 1, ingestion into the stomach and 2, aspiration into the air passages of products of cell disintegration, of fermentation, and of putrefaction together with innumerable microorganisms of one or other squad. On the other hand, when the sepsis is closed or shut off there will be some spread through bone by lymphatic or by vascular channels, of the infecting organisms, and gradual absorption, from the pentup focus of toxic products, with perhaps one day a *sortie en masse* resulting in a septicemia of one kind or another. And this is what we do find happens, in the clinical field, where, however, the two types of sepsis may exist side by side.

We can now see how complicated are the evil possibilities of dental sepsis, and how it is that, in actual practice the consequences are so manifold and so little specific. We see, too, how credulous are those who believe that there are defined limitations to the evil that may be wrought by dental sepsis, and how unscientific is the attitude of mind that leads to loose talk about the "modern craze for attributing all maladies to bad teeth."

The captains of disease and death have other squads under their command than those of the workers of dental sepsis; they have none more efficient, or more active.

DIISEASES CORRELATED WITH ORAL SEPSIS

We may now consider the various diseases and morbid states that we believe are correlated with oral sepsis and may therefore truly be said to be oftentimes caused by it.

Of all these, one—neuralgia major, or *tic douloureux*—stands by itself. Not every case deserving this name can be considered as caused by dental sepsis but, in a certain number of cases, this terrible malady appears to follow the continuance of a chronic periodontitis, or an ascending neuritis from chronic osteitis of tooth sockets (Horsley). Neuralgia minor, on the other hand, when associated with dental disease, is best regarded as symptomatic: that is, as a sign of dental disease.

The diseases and affections commonly consequent to oral sepsis may be conveniently discussed under four headings:

1. Local affections of the mouth and associated parts.
2. Affections of the gastrointestinal tract.
3. Affections of the respiratory tract.
4. General states, and affections of the endocrine, nervous, and other systems, arising from absorption or infection.

Obviously, conditions falling into categories 1, 2 and 3, will in general arise from local spread, from ingestion and from aspiration, while those referred to under 4 will usually be connected with the entry of toxins or of organisms into the lymphatic and vascular channels.

LOCAL AFFECTIONS OF MOUTH AND ASSOCIATED PARTS

To consider first the local affections of the mouth and associated parts. A generally unhealthy state is set up which may spread by direct extension, which may predispose to acute intercurrent maladies, which

may be followed by definite secondary infections, and which may lead to chronic degenerative processes. Various forms of tonsillar and pharyngeal implication thus occur, with sometimes extension to the Eustachian tube and middle ear. Chronic glossitis is set up, and sometimes is followed by cancer. Steno's duct may be infected with sometimes acute, and possibly chronic affection of the parotid gland. Acute cellulitis may involve the tissues beneath the deep cervical fascia (angina Ludovici), and various forms of erysipelas affecting the lips and face arise. Vincent's angina is generally regarded as secondary to gingival infection and, when there is preexistent oral sepsis, the angina of scarlet fever and diphtheria is aggravated. Spread by certain routes leads to infection of the maxillary and other sinuses; sometimes with orbital periostitis and cellulitis. In the latter case, ocular troubles may ensue, but the connection of these with oral sepsis, apart from obvious orbital cellulitis, is well recognized. Lang has elucidated the connection of optic neuritis, retrobulbar neuritis, interstitial keratitis, scleritis, episcleritis, iritis, iridocyclitis (with cataract and glaucoma), choroiditis of different forms, and progressive myopia, with oral sepsis.

Implication of the submaxillary and submental lymphatics, with spread to the cervical glands, and later to those in the mediastinum, may attract attention if acute, and do much damage if chronic.

A simple chronic lymphadenitis from oral sepsis is sometimes followed by tuberculous disease, or by lymphadenoma. The importance of the connection between oral sepsis, chronic lymphadenitis and chronic mediastinitis, leading to pulmonary and cardiac complications I believe to be very great. The association is probably at the bottom of not a few of the chronic degenerative intrathoracic affections.

Absorption into and infection of the blood stream or lymphatics may of course take place at any point in the mouth where there is no efficient tissue barrier, but the consequence of such infection will be more conveniently dealt with later.

AFFECTIONS OF GASTROINTESTINAL SYSTEM

Passing to the gastrointestinal system, we note, first, the hindrance to efficient digestion that arises from the conveyance of septic filth and cellular débris with organisms of all kinds, into the stomach itself. Vital and chemical activity is hampered and, first, the stomach walls, later those of other stretches of alimentary canal, become catarrhal, inflamed, and perhaps atrophied. Clinically, we recognize various types of septic or fermentative dyspepsia as associated with gastric dilatation. Acute ulcer is probably often a result of the septic infection of a small, or microscopic trauma; chronic ulcer is aggravated by gastric sepsis. Not only duodenal ulcer, but duodenal catarrh, is related to oral sepsis, and, once the duodenum is unhealthy, the gall vessels and liver become easily involved, leading to gallstones, and various infective and degenerative conditions. The liver, like the thyroid and other organs, has a definite part to play in defence against toxins and microorganisms. We cannot forget this in considering the causes of functional failure and organic change in these organs.

It is practically certain that some forms of acute and chronic pancreatitis are the result of ascending infection of the pancreatic ducts. So perhaps we have one explanation of the constant association, with diabetes, of oral sepsis. Except in children, diabetes is rarely seen in persons who have clean mouths.

Chronic enteritis is often an extension of what is present in the stomach and duodenum; the appendix is a lymphatic accessory of the bowel, in effect, and is affected by what affects it. There is no doubt of the close association of many forms of colitis with oral sepsis. Here the clinical evidence is very strong except, of course, in respect of the purely nervous cases.

A remarkable fact is that anal piles and other affections are often associated with oral sepsis, and this may be diversely explained.

Experience at St. Mark's Hospital led me to believe that persons who have a vulnerable stomodeum have a no less vulnerable proctodeum, and so possibly this apparent "sympathy" of distant parts has a biological connotation.

That cancer supervenes in tired tissues the subject of long continued irritation must not be forgotten when we seek into its remoter antecedents, while constipation, in some of its severer as well as its milder forms, is sometimes the result of a neuromuscular debility that is in part the consequence of long continued poisoning or tissue infection by septic organisms.

Whilst there has been, on the part of many, very full admission of the part played by oral sepsis in the production of disease of the alimentary system, recognition of its relation with disease of the respiratory system has been less full. Certainly, disease of the respiratory system, more frequently than disease of the alimentary system, is connected with sepsis of the nose and adnexa.

AFFECTIONS OF RESPIRATORY TRACT

But still, oral sepsis has much to do with respiratory disease. The route to the lungs, via the cervical lymphatics, the mediastinal glands, and the pleural spaces has been already pointed out. There is also the direct route, followed by aspirated material, especially when mouth breathing continues during sleep.

Certainly the dangers of oral sepsis, quâ the respiratory system are much greater in those who are already the subjects of nasal obstruction, of asthma, and the like; so much must be admitted. Under these circumstances, chronic laryngitis, bronchitis, and bronchiolitis may become established, entailing bronchiectasis and other chronic conditions, as well as the liability to acute intercurrent maladies.

A special liability to respiratory complication affects those who submit to surgical operation requiring oral administration of anesthesia while suffering oral sepsis to continue, and those surgeons lose most patients who neglect to assure themselves of the mouth condition before operating.

Even if we disallow the influence of oral sepsis in paving the way for infection by the Bacillus tuberculosis we cannot deny that fatal tuberculosis of the lungs is frequently the result of a mixed infection, in which streptococci from the mouth are accomplices, while pulmonary strepthricosis seems to be definitely a gum infection at first. Gangrene of the lungs, and septic or putrid bronchitis, are secondary lung conditions often associated with oral sepsis.

GENERALIZED BLOOD INFECTION

The results of generalized blood infection cover almost too wide a field for easy exploration. But we must recognize, in the first place, a more or less definite form of debility with malnutrition, simple anemia, and slight fever, that is a result of oral sepsis. In other cases certain socalled cryptic forms of septicemia and pyemia are dental in origin. The grave form known as malignant, septic or ulcerative endocarditis is certainly sometimes due to blood infection from the teeth and gums.

Since the work of Hunter some twenty years ago increasing attention has been given to oral sepsis in connection with grave anemia. We now distinguish, 1, simple secondary anemia, associated with oral sepsis; 2, grave septic anemia, certainly due to mouth infection, and 3, hemolytic (pernicious) anemia with glossitis also, but less definitely or directly, associated with oral sepsis.

In connection with these blood states we may speak in general terms of various degenerative conditions of the heart walls and of the bloodvessels, as well as with toxic neuroses of the heart, and other organs.

These toxic blood states may also be invoked to explain, and probably with reason, in part at least, certain neuroses and psychoses of central origin, as well as some forms of neuritis. The fact that certain degenerative diseases of the spinal cord are associated with severe anemias has led to consideration of the influence of oral sepsis on cord and nerve degeneration.

Among the disorders of metabolism that seem connected with oral sepsis, gout seems to hold a place, though in this respect its influence is perhaps only indirect.

MYXEDEMA

Other affections require mention: among them myxedema is prominent. Myxedema sometimes represents a failure of the thyroid to cope with the calls upon it by way of defence against poisons and infections. Since oral sepsis is one of the commonest of infections we can see how sometimes it exhausts the thyroid, and why it is that thyroid deficiency is so often an accompaniment of arthritis.

JOINT AFFECTIONS

The joint troubles consequent to oral sepsis are oftentimes very serious. In acute rheumatism it may be that the infection we believe to be present occurs by way of the mouth; in some other joint affections it certainly does. We may distinguish, 1, the obvious septic arthritis; 2, rheumatoid arthritis and 3, osteoarthritis. It is with the two last that we are now most concerned.

Rheumatoid arthritis occurs in several clinical forms, but it is rarely that some septic focus, some source of chronic infection cannot be discovered. Very frequently this is in the mouth. In osteoarthritis, mouth infection is often present but the beneficial results of dental treatment, though important, are less happy than is often the case in rheumatoid arthritis. A rough distinction between rheumatoid arthritis and osteoarthritis may be made in saying that the former affection is generaly polyarticular, and involves small joints with marked periarticular changes while, in osteoarthritis, one or more large joints are implicated and there is bony and cartilaginous change). Rheumatoid arthritis is often more purely septic than is osteoarthritis, in its origin; the latter malady is often connected with mechanical stresses, static or traumatic. Fibrosis in the region of joints is frequently toxic or septic in origin.

Whilst it is true that some, nay, many, of these joint affections are properly traceable to oral sepsis, it must be frankly admitted that the hope of cure sometimes held out, if wholesale extraction be permitted, is really not justified. It is right to cut off the further supply of sepsis; but, too often, irreparable damage has been done to the joints before dental treatment is carried out. It seems too sometimes as if these joints act as what the French call *abcés de fixation,* and so the patient secures immunity at the expense of crippled joints. Certainly, joints seem to play a part in defence reactions; the joint troubles of serum sickness will at once recur to the mind.

WIDESPREAD INFLUENCE OF ORAL SEPSIS

One word more must be added. The influence of oral sepsis in the production of disease is not limited to its subject.

Mr. Pierrepont (4), in particular, has shown that maternal oral sepsis sometimes exerts a most prejudicial effect on the fetus and on the nursling. Lactation may be gravely interfered with, and even when the mother does not suckle her child she may infect, from her mouth, the comforter or the bottle teat. Again, it is evident that no wet nurse should be selected whose mouth is not above suspicion.

CONCLUSION

Looking back over the whole ground thus cursorily covered it is clear that, on the one hand, as already said, it is impossible to impose any definite limit to the mischief we may properly ascribe to oral sepsis under certain conditions. On the other hand the zeal of doctor or dentist must never allow him to say, 1, that because such and such a condition is present there must be oral sepsis, or 2, that because oral sepsis is present this patient must either be ill now or in the near future. Again, it must not be said that, because oral sepsis and some other condition is present that the conjunction of the two is reason for all. There may be some other focus of infection, some other factor present. Complete examination and the fullest consideration of all relevant circumstances are necessary.

In face of such difficulties as do arise in connection with this subject, the practitioner will do well to think in terms of sick persons, rather than in terms of diseases. Textbook descriptions are necessary and are helpful, but, in practice, we deal primarily with particular persons.

Scientific practice is guided by *reasoning* based upon *experience* and *observation;* it is not based upon adhesion to authority; that leads to dogma. Nor is it based upon mere observation; observation and experience, without reasoning, constitute mere empiricism.

Pneumonia During the Past Ten Years*

RUDOLPH DURYEA MOFFETT, M.D.
New York

Observations presented in this paper are from personal experience on the pediatric service of the Lenox Hill Hospital, New York, from January, 1915, to May, 1925. During this period there have been 495 cases of pneumonia, of which 249 were lobar pneumonia and 225 were bronchopneumonia. The number of deaths was forty-nine, a total mortality of 9.9 per cent., which is considerably lower than the usual reports from hospital services. These cases of pneumonia do not include any patients that were in the hospital less than twenty-four hours or any cases from the contagious service. In twenty-one cases in which the histories were incomplete, the exact type of pneumonia could not be determined. The greater number of patients came from the middle and poorer classes in the immediate vicinity of the hospital. The ages varied from a few months to thirteen years, and the number of males was slightly in excess of the females.

The majority of these children admitted to the hospital had high temperature and rapid pulse rate ranging from 130 to 140, being rarely out of proportion to the markedly increased respirations, which ranged from 40 to 60. In this series of cases, in which digitalis was instituted early, we never observed the sudden drop in pulse or the cardiac collapse which is frequently present at the crisis. The pulse rate continues regular, always slightly lower, and gradually comes down to normal. The respirations are markedly increased and appear on the chart as a line always above the temperature curve, remaining there until the termination of the illness. Active movement of the alæ nasi associated with labored breathing, ending in typical pneumonic grunts, is the familiar clinical picture. With each respiration there may be intense pain caused by the inflamed pleura covering the lung rubbing against the chest wall. If this condition is present, the pain continues for a few days until there has been an accumulation of fluid between the two layers of the pleura, which prevents any friction from taking place with respiration. In the uncomplicated lobar pneumonia the temperature remains high, varying from 103.5° to 104.5° F., with very little change until the time of crisis, when it may drop to 99° or below normal.

In bronchopneumonia of the influenzal type there are very wide excursions of temperature which go up and down from 101° to 105° F. throughout the entire course of the illness. In most cases of lobar pneumonia the temperature drops two or three degrees on the day before the crisis, but within a few hours it rebounds to 104° to 105° F. This is called the precritical drop and is followed the next day by the real crisis, which in this series occurred from the fifth to the seventh day, when the temperature remains normal with the convalescence of the patient.

*From the Lenox Hill Hospital, A. Jacobi Division for Children, Dr. A. L. Goodman, director. Read before the Section on Diseases of Children of the American Medical Association, Atlantic City, N. J., May, 1925.

In lobar pneumonia the right upper lobe was more commonly diseased than any other portion of the lung, although any other part may become affected. Patients with bronchopneumonia were affected with the influenzal type and were more acutely ill than those with lobar pneumonia. The more serious cases occurred in both forms of pneumonia when there was inflammation of the apex alone. This is probably due to the fact that absorption takes place more easily into the general circulation, with the development of more general toxemia, when the apex is involved than when the base is involved. Certainly the type of infecting organism determines the severity of the toxemia and the prognosis of the case. However, patients with low temperature may manifest symptoms which are more severe than those of patients with considerably higher temperature.

LABORATORY EXAMINATIONS

Laboratory tests, especially the examination of the blood, aid in determining the type of infection and prognosis of the case. The presence of a high leucocyte count may indicate a more marked resistance to infection. In lobar pneumonia the leucocytes may be as high as 50,000, with polymorphonuclears of ninety per cent. A low leucocyte count with not more than fifty per cent. of polymorphonuclears indicates a lessened resistance and is always found in influenzal pneumonia. Daily blood examinations should be made in all acutely ill children, especially when complications arise. In my series of cases, the highest number of white blood cells was 55,000 and the lowest number was 8,000. Cultures were taken from the blood in a small number of cases, but in no instance was an organism obtained nor was this test of any assistance in confirming a diagnosis.

Throughout the entire course of the illness, complete urine examinations should be made daily for the detection of nephritis. At the beginning of the disease there may be faint traces of albumin with casts, caused by the fever; if this persists it may develop into a severe nephritis and cause as much anxiety as the pneumonia. Of equal importance to the examination of the urine is the daily measuring of the fluid intake and the quantity of urine excreted in twenty-four hours. During the height of the disease there may be a small amount of concentrated urine due to the lessened fluid intake and the retention of fluids in the body. Of numerous chemical examinations of the blood made during the course of acute nephritis in pneumonia, only slight chemical changes were found. This was of little value in the prognosis, as the figures varied slightly from the normal.

In the typing of sputum for organisms, the largest percentage of specimens contained bacteria which came under Group 4, for which there is no serum. It has been so difficult to obtain a sufficient quantity of sputum from small children that grouping has been scarcely worth while.

RÖNTGENOGRAPHIC EXAMINATIONS

In hospital work in which röntgen ray examinations are available the chest should be röntgenographed in all cases. This is of great assistance in the presence of a doubtful diagnosis, especially when there may be a question of pneumonia or appendicitis. Without physical signs, except dullness, the röntgen ray may confirm the diagnosis. It has been my experience that if daily pictures are taken the preliminary shadow which appears on the surface of the lung gradually increases in size until it assumes somewhat the shape of a wedge, the base of which is on the surface of the lung and the apex extends inward until it comes in contact with a large bronchial tree. This is just the reverse picture to that which one sees in embolism of the lung. The slow development in the shape of the area of consolidation accounts for the frequent delay in hearing the bronchial breathing. The bronchial breathing is not transmitted through the diseased lung until the apex of the triangle has extended to one of the bronchial trees. In the majority of cases there were more or less distinct markings which were reported as pneumonia. In a small number of cases in which a definite diagnosis could be made by physical examination the röntgenogram was negative. The difficulty that sometimes arises in cases of suspected pleurisy or empyema as to the presence of fluid may be demonstrated successfully by the röntgen ray. The type of shadow cast by the fluid in the pleural cavity depends on the quantity and density of the fluid present. In simple pleural effusion the shadow may be very slight, while in empyema the shadow indicating fluid may merge with the consolidated portion of the lung, rendering it difficult to differentiate between the extent of the fluid and the extent of the consolidation.

COMPLICATIONS

The most common complications that occurred during the course of the disease were otitis media, pleurisy, empyema, myocarditis and nephritis. In this series there were comparatively few cases of otitis media. The ears should be examined every day during the height of the pneumonia for development of middle ear disease, such as redness and distinct bulging of the drum. If this occurs, two courses are open: 1, to allow the drum to rupture spontaneously; 2, to incise the drum early for the evacuation of pus. The latter course is considered the more favorable as it lessens the amount of inflammation and relieves the pressure of the confined fluid.

In almost every case of pneumonia there is a small amount of pleural effusion at the site of the pneumonia. This, an inflammatory reaction, is due to the two inflamed surfaces of the pleura coming in direct contact. Fluid is usually determined by physical examination, the röntgen ray and chest tapping. The physical signs that are commonly present are flatness, loss of tactile fremitus, and diminution of the breath and voice sounds. The early pleural effusion that occurs is not of any serious consequence when the fluid remains clear and is not too extensive, as it is quickly absorbed after the temperature has come down to normal. However, thirty-five cases had a sufficient amount of fluid to interfere with respiration and were classified as pleurisy with effusion. Twenty-six of these patients developed empyema; five died. In children the physical signs of fluid differ from those in adults; fluid creeps up the lateral chest wall, making a distinct parallel line to the lung and not parallel to the diaphragm as in adults. This may be demonstrated by the röntgenogram. When the pleural cavity becomes so filled with fluid as to embarrass the respiration or displace the heart, the fluid should be aspirated with the Potain negative pressure apparatus, never taking off more than one half of the estimated fluid present as the too rapid removal of fluid from the pleural cavity may produce pleural shock, edema of lungs and collapse. The remaining fluid may be aspirated within a few days. The point of aspiration should be wherever the signs are present or at the classic angle of the scapula. Simple puncture for the removal of fluid sometimes hastens the absorption; another method that may be advised is the subcutaneous injection of ten c.c. of sterile pleural fluid. Cultures of all aspirated fluid should be taken to determine the type of organism, as this decides the procedure to be followed should empyema develop. If the aspirated fluid is cloudy and contains pus with organisms, the case should be considered as one of empyema.

In this series of cases the most common organism was the pneumococcus, the next the streptococcus, and then the staphylococcus. If the pneumococcus is the organism recovered, there is no immediate necessity for draining the pleural cavity; but if the streptococcus or staphylococcus is present, surgical intervention is urgent, as infections with these organisms are more severe and are more likely to produce general sepsis. In the former the fluid usually becomes very thick with the formation of fibrin and adhesions, whereas in the latter the fluid may become cloudy with very little fibrin or adhesions. From the surgical viewpoint the type of organism present is of paramount importance, as most surgeons determine their surgical procedure on this point. It has been found best to delay opening the chest, especially in pneumococcus infection, until the fluid becomes very thick; this permits adhesions to form and prevents early collapse of the lung. An empyema operation should never be performed at the height of the pneumonia, but should be delayed so as to permit the pneumonia to subside completely and the patient's general condition to improve, except, as stated above, when the streptococcus is the invading organism. Early operations in cases of empyema have a high mortality due to the following causes: severity of the infection, collapse of lung with circulatory disturbances in the mediastinum, and diminished area for breathing on opposite side.

The three following methods for the treatment of empyema are in common surgical usage at the present time: 1, simple aspiration; 2, closed method (suction drainage of cloudy fluid), and 3, open method (resection of rib). The closed method often gives ample drainage to empty completely the empyema cavity, or this may be used as a preliminary step to the open method, allowing the patient more fully to overcome his toxemia. With the open method, Dakin tubes may be inserted into the pleural cavity for complete flushing and sterilization.

Early in the disease, distinct signs of myocarditis may develop, which are manifested by weakening of the heart sounds, rapid feeble pulse, and disturbed circulation, characterized by blueness of the lips and clammy, cold extremities. This condition is caused by two things—toxemia and the unaccustomed strenuous burden that is thrown on the heart during the pneumonia. The myocarditis, if severe, may be one of the causes of death at the time of crisis, and indicates the necessity of stimulation from the very onset of the disease. After the temperature has been normal for a few days, the heart sounds markedly improve with a gradual disappearance of all signs of myocardial involvement.

Another complication that must be guarded against is the possible development of nephritis. This does not ordinarily occur, but when it does it may be of serious consequence and cause permanent injury to the kidney. The daily measuring of the amount of urine excreted is an important guide in determining the amount of kidney function. The quantity of urine excreted should be about equal to the fluid intake. In my experience, with proper treatment and careful watching, even a severe nephritis may be bridged over to a complete recovery.

TREATMENT

The treatment that we have followed for the last ten years has consisted of proper hygienic surroundings, fresh air, efficient nursing, sponge baths, proper diet, and medication. Whether in the home or in the hospital, children with pneumonia should be isolated throughout the entire course of the illness, except when there are several children in the same stage of pneumonia. Even these children should be separated by glass partitions or screens to prevent bedside infection. Each room should be well ventilated with cool fresh air at a temperature not below 50° F. Some years ago the use of cold air was urged as a form of treatment in pneumonia, as this was helpful in raising the blood pressure. We have never found the use of icy cold air of any benefit, but on the contrary somewhat of a detriment, especially in weak, exhausted children, acting more as a depressant rather than a stimulant. Our experience has been that the best results in regard to ventilation are obtained with an even temperature of from 50° to 60° F., with no sudden changes from heat to cold. Whenever there is high temperature, regular sponge baths every three hours with water at a temperature of 100° F., combined with an ice bag to the head and a hot water bag to the feet, reduce the fever from one to two degrees and allay much of the restlessness and delirium. These measures tend to lower the temperature, and we have never found drugs necessary. The daily use of a five per cent. solution of sodium bicarbonate as a rectal irrigation assisted by mild cathartics from above relieves much of the extreme toxemia and restlessness. A liberal amount of forced feeding should be persisted in, such as, milk, eggnogs, white of egg with orange juice, cocoa, thin cereals, and purée of creamed soups. Nourishment should be given at regular intervals with the insistence of cooling fluids in between the feedings to obtain further elimination of toxemia.

All forms of medical treatment have been suggested in pneumonia. We have found that the early use of stimulation from the very onset of the disease with such preparations as digitalis, camphor and caffein sustains a weakened heart muscle and greatly lessens the mortality. These drugs should be used in large enough doses at regular intervals to produce a full physiologic effect—small doses are useless. From the beginning of the illness, during the first forty-eight hours, even in young children, we give one drop of the tincture of digitalis for every pound of body weight. This may be divided into regular doses to be given at fixed times. For example, a child weighing twenty pounds would receive two drops of digitalis five times during the first day and two drops five times during the second day. This would make a total of twenty drops during the first forty-eight hours; after that the dose may be reduced, depending on the patient's condition, to one half the amount in twenty-four hours until after the crisis. In each case the quantity of digitalis should be individualized according to the response and effect on the pulse. In older children the fluidextract may be given in one to two minim doses four times a day. It is not as beneficial nor is it as well tolerated by the stomach as the tincture. In extremely toxic cases with very rapid heart action the hypodermic use of digitalis, preferably in the form of digifolin, produces a rapid digitalizing effect without any irritation to the stomach or inconvenience to the child. It may be used when there is vomiting or when there is difficulty in giving the child fluids or medication.

Whenever digitalis treatment is instituted, the pulse rate should be carefully watched for any sudden changes or any marked slowing of the pulse. One is often surprised at the large doses of digitalis that may be given without disturbing the patient. A very safe rule for the use of digitalis is the one given above, and in our experience it has proved beneficial in a large number of cases.

As a second stimulant and support to the heart, camphor in one of two forms may be used: 1. The camphor emulsion made according to the following formula; monobromated camphor, two gm.; mucilage of acacia, eight c.c.; olive oil, eight c.c., and sufficient water to make 120 c.c.. This has proved an excellent stimulant and is fairly well tolerated by the stomach. 2. In the presence of vomiting or any difficulty in giving medication, a twenty per cent. solution of camphor in oil of sweet almond is used hypodermically. There is no definite dose for camphor; it may vary from one to three gr., depending on the age and weight of the child. It should always be used in conjunction with digitalis, as it seems to have some decided effect on the pneumonia and is also an excellent expectorant.

When a rapid stimulant is desired, before the digitalis has begun to act, caffeine sodiobenzoate in from one to two gr. doses given hypodermically acts very rapidly, but it is not as desirable as digitalis or camphor. The objection to its use is the marked restlessness and irritability of the patient after it is given. It has been our practice in all cases of marked delirium and extreme toxemia, especially when there is very high temperature, to use medium sized doses of whisky well diluted in water. This applies to cases in which there is marked sepsis.

While I know that whisky is condemned by a large majority, it certainly has been of great benefit in our treatment of pneumonia. All these drugs should be continued throughout the entire course of the disease and not discontinued until the temperature has been normal for at least twenty-four hours. Regardless of which stimulant is used, one should always give it early in full doses at regular intervals until after the crisis. From my experience and observation in the treatment of pneumonia in infants and young children during the last ten years I cannot help but feel that during a period of continued high temperature with marked toxemia, an injured heart is better supported and better able to withstand the strain when stimulation is begun early and continued in sufficient quantity throughout the entire course of the illness.

70 East Seventy-seventh Street.

The Prevention of Scarlet Fever*

JAMES C. SMALL, M.D.
Philadelphia

An intelligent prevention of an infectious disease, as well as its treatment, must depend on definite knowledge of its cause. The cause is a living microscopic agent, which differs for the different diseases, but usually belongs to the group of organisms known as bacteria. These bacteria usually invade the host in which they produce disease through some very definite portal of entrance. For our purpose we will consider only those microorganisms which gain entrance through the nose and mouth and find lodgment in the upper respiratory passages. Such bacteria are most commonly transferred from person to person through the medium of droplet spray of the upper respiratory secretions scattered broadcast by the infected individual in acts of sneezing, coughing or talking, and are breathed in by the next individual in whom they are to produce disease. One may call this direct aerocontact transmission. Upon implantation on the surface of the membranes lining the nose and throat the first requisite in the production of disease is the ability of the virus to reproduce and multiply in this location; the next is its ability to invade the tissues. This property of invasion is spoken of as virulence of the microorganism and differs for different bacteria. Immediately the microorganism begins to invade the tissues the body defences against such invasion are called into play. If these body defences are successful in resisting the invasion of the microorganism, its implantation in that particular individual is incidental and passes unnoticed because no noteworthy symptoms are produced. If, however, the body defences are not prepared to combat successfully the invasion of the microorganism, serious manifestations of such invasion result. Some types of bacteria are aided in their attack upon man by a property which they possess upon growth of producing a powerful poison or toxin which paralyzes the individual's forces of resistance to the invasion. Some persons have already in their blood antitoxin which serves to neutralize this toxin of the bacteria. In these persons the invasion of the bacteria is successfully resisted, and the person is spoken of as immune to the infection. Those who do not have this antitoxin are spoken of as susceptible to the infection.

Some bacteria which produce these toxins when they grow naturally in our tissues, may be grown artificially in the test tube under conditions whereby they produce the same toxin. Given such a toxin in the test tube for a particular disease, we can use it for three purposes in combating the disease. First, we can inject minute amounts into the skin of normal individuals and obtain definite knowledge from the nature of the trifling local reaction which follows as to whether the person is or is not susceptible to the disease in question. Second, after having determined in a group of persons, those who are susceptible to the disease, we can by using injections of larger amounts of the toxin excite the production of antitoxins in the blood of such persons so that they are no longer susceptible to the particular disease. Third, we can inject animals with repeated doses of the toxin and obtain in the blood serum high concentrations of antitoxin. The serum from such animals can then be preserved and used in neutralizing the toxins which happen to be producing serious acute illness in a given individual.

Bearing these general principles in mind, let us consider more specifically how they apply to scarlet fever. It appears obvious that their application must depend first of all upon knowledge of the specific bacterium causing scarlet fever. This has been the riddle of scarlet fever which was solved only recently. Scarlet fever was known to the medical profession for many years before the era of bacteriology made it possible to search for a specific microorganism as its causative agent. The first unmistakable account of scarlet fever was by Daniel Sennet of Wittenberg (about 1625), but it was Sydenham in 1675 who gave the first full account of the disease under the name *febris scarlatina*. Common in Europe during the eighteenth century, it appeared in North America, according to Craigen in 1735, spreading throughout New England, thence to New York in 1746. With the beginning of the era of bacteriology in the nineteenth century, interest was aroused in a search for the causative bacterial agent. Certain bacteria (streptococci) were associated with the sore throat of scarlet fever almost from the first. Streptococci were, however, found in association with many other abnormal conditions not at all akin to scarlet fever. Therefore confusion arose, and since it was not then appreciated that there are many kinds of streptococci, all resembling one another closely, it came to be doubted whether the streptococci actually found were the real primary causative agents in scar-

*Delivered before the Section of Public Health and Industrial Medicine, College of Physicians, Philadelphia, Pa., March 13, 1925.

let fever, or whether they were simply concomitant agents causing certain of the complications of the disease, but not actually instituting the disease itself.

A ray of light was shed upon the real cause of scarlet fever in 1902, when Moser and von Pirquet, using streptococci isolated from patients with scarlet fever, prepared in animals a serum which in their hands yielded hopeful results in the treatment of scarlet fever. There can be little doubt that the nature of the disease was almost discovered at this time. Several other workers confirmed these good results with serum, but shortly a number of others failed with serums prepared after the method of Moser, so that after a period the matter of a specific action of a streptococcus serum in curing scarlet fever was dropped.

The idea of a filterable virus (i. e., an organism too small to be seen by the ordinary microscope) came to be more or less popular as an explanation of the causative factor in scarlet fever.

The next important contribution bearing on the cause of scarlet fever was made by Miss Tunnicliff in Chicago in 1902, when by complicated laboratory procedures she showed that the streptococci occurring so constantly in the throats of patients with scarlet fever constituted a particular group, and that the members of this group while similar one to another differed from the streptococci derived from sources other than scarlet fever. She showed further that patients with scarlet fever early in the course of the disease possessed little power to fight off infection with this particular streptococcus, but that during convalescence they possessed this power to a greater degree than normal individuals. This important contribution did not at the time receive the attention which it deserved, largely due to our heritage of misconception in regard to the cause of scarlet fever. In 1918 the observation was made that convalescent serum possessed the property of blanching the rash of scarlet fever in a local area about the site of an injection of it into the skin. (The Schultz-Carlton phenomenon.)

From this on the work which has led to our present conception, and what is without doubt the true conception of the nature of scarlet fever, culminated rapidly. Two groups of workers were concerned in bringing about the solution of the riddle of scarlet fever. The eastern group composed of Dochez, Avery, Lancefield, Bliss, Sherman, Blake and the midwestern group, George and Gladys Dick working in Chicago.

The contributions of the former group consisted of the development of better methods for differentiating different strains, the confirmation by this method of the occurrence of a particular variety of streptococci in scarlet fever patients, the development of a specific serum for treating patients suffering from scarlet fever, and the demonstration of the curative effects of this serum in the treatment of such patients.

The work of the Dicks stands out as epoch making because of two things. First, they appreciated the fact that the real reason for lack of progress in the solution of the problem was the lack of susceptibility of experimental animals to inoculations with scarlet fever. They therefore departed from the beaten course in experimental work and used humans for inoculation purposes. In doing this they were the first to show that the streptococcus from scarlet fever patients produced this disease when inoculated into susceptible humans. Secondly, they produced in the test tube the toxin elaborated by these streptococci, and with this toxin once in hand they developed a skin test enabling one to pick out susceptible persons from those not susceptible to scarlet fever; they produced symptoms resembling those of scarlet fever by the injection of proper doses of this toxin alone; they were able to show that susceptible individuals can be rendered nonsusceptible by the use of injections of this toxin; and that an antitoxin could be prepared in the blood of animals which could then be used in neutralizing the toxins causing the acute attack of scarlet fever.

The present conception of scarlet fever then is that it is caused by a streptococcus growing usually primarily in the throat, where soluble toxins are produced and diffuse outward to give rise to grave general symptoms. The complications and sequellæ are partly due to residual effects of the grave toxemia and partly due to invasion and local development of the bacteria in points adjacent or far removed from the initial site of the infection in the throat.

Barring complications of the latter type the streptococci disappear rather rapidly from the throat in most instances. If they invade the accessory sinuses, the middle ear, the glands of the neck, and other parts, the organisms persist for long periods. In fact such individuals may become permanent carriers of these bacteria and at any time serve as the medium for infecting others. Persons who are immune to scarlet fever may when in contact with acute cases of the disease for a time harbor these organisms in their throats presenting either no local symptoms or only mild local signs of inflammation. (These may be called contact carriers.)

The acute carrier (i. e., the patient with scarlet fever) is the chief source of danger in the spread of the disease, the permanent carrier and the contact carriers are the other sources of danger, chiefly important because they frequently go unrecognized and thus serve in maintaining the endemic characters of the disease.

This rapid transfer from susceptible individual to susceptible person is important in that it seems to increase the virulence of the organism. It may, in large part, account for the great variations noted in the severity of different epidemics of scarlet fever.

In the prevention of such a disease as scarlet fever there are two general plans of attack: First includes measures taken to prevent the spreading of the causative agent; and second, includes measures taken to render susceptible persons nonsusceptible to the disease.

The first has heretofore failed to eradicate the disease although it has been to a certain extent instrumental in controlling epidemics. Greater success with these methods is not likely to eradicate the disease even now with our better understanding of the nature of the causative agent.

The logical point of attack, where failure to control the spread of the streptococcus is admitted, is that of rendering susceptible persons immune to the infection. Many persons are naturally immune and therefore need no treatment.

The skin test made with the toxin of the strepto-

coccus of scarlet fever, known as the Dick test, enables the identification of those who are likely to be attacked by the disease given the opportunity for contact with it. This class of individuals varies from roughly twenty per cent. to eighty per cent. of given groups, varying widely with the age, and the opportunities for previous exposure to the disease. Children show higher percentages of susceptibles than do adults; children of the well to do higher percentages than children of the poorer classes.

Having determined susceptibles, these are rendered immune by the injection of graduated doses of the toxin, beginning with not more than one hundred times the dose employed for the skin test for the first dose; repeating with two and one half times this dose after a week; and giving still a third dose of from two and one half to five times the first amount used.

Now you will naturally ask, is not all this so new that it is really yet in the experimental stage? Yes and no.

The Dick test followed by immunization of those shown to be susceptible has been practiced upon thousands of individuals notably by Zingher in New York. Both procedures have been shown to be reliable and efficient. Naturally it may be expected that the present practice in the application of these principles does not represent final perfection. Difficulties are to be expected in any complicated biological procedure. One outstanding difficulty in this procedure is the matter of accurately measuring the strength of the toxin in the products to be used. At present the strength of the toxin is measured in terms of the amount that will produce a certain type of reaction when injected into the skin of known susceptible individual, volunteering for this purpose. It is obvious that this does not permit of as accurate an estimation as would be desired. We need to know more about technical matters in the production of this toxin. Again it must be expected that considerations other than enthusiasm for the prevention of scarlet fever may place on the market inferior products for this work. The public is protected in such matters by certain standards imposed by Federal law and there is little doubt that adequate supplies of reliable products will soon be available.

The big task which faces those interested in preventive medicine in this matter is the application of these methods in communities of persons. The discovery of a law or of principles beneficial to a community does not in itself benefit the community. It is the application which benefits.

Some one has said, that one of the difficulties with constitutional government is—"that governments move on, while constitutions stand still." More and more in these days of preventive medicine do we find its progress hampered by our code of medical ethics, which has not been revised to meet the needs of preventive medicine. Preventive medicine needs ways and means to parade its stock in trade before the public eye. Medical societies should take a lesson from modern business corporations. The radio business was not built up so quickly to present proportions through public meetings and personal appeal. Certainly people desire health more than they long for a radio apparatus, if they are only made to realize it. They can be made to realize it by the use of proper appeal from medical societies through the medium of the press. This appeal should give definite instruction in the benefits from the practice of these principles; should show the failures of methods formerly practised; should specifically direct persons to their family physicians; should give them an idea of the relative insignificance of subjecting themselves to the procedures; and give some approximation of the expense involved. Most important of all such appeals should be repeated daily for long periods and properly placed in the advertising columns of the newspapers.

The educational program which has been employed in connection with diphtheria prevention should aid in this program for prevention of scarlet fever. The methods of arousing interest in both of these important procedures should, however, be changed, especially since those employed in the diphtheria work cannot be called highly efficient.

Congenital Diaphragmatic Hernia with Complete Rotation of Stomach

N. ALPERT, M.D.

Baltimore, Md.

Although medical literature abounds in diaphragmatic hernias, many of which have been reported in recent years, the diagnosis in many instances has been made by the röntgen ray examination. As far as we can ascertain, this report represents the first case on record of congenital diaphragmatic hernia with a complete rotation of the stomach.

Case.—Mr. H. H., aged twenty-two, American, of Jewish parentage, single, a shoe salesman, was referred to me on May 18, 1924.

Family history.—Father living and suffering from gastrointestinal disturbances. Mother living, troubled with hyperthyroidism. Family negative to tuberculosis, cancer, and cardiorenal disorders.

Past history.—Patient weighed five and a half pounds at birth. He was breast fed for a short time. There was considerable gastrointestinal trouble following the establishment of artificial feeding. On two occasions he had convulsions which were considered the results of gastric disturbances. He was a delicate baby, undernourished, and very irritable, always suffering from constipation. He had had measles at the age of two; pertussis and pleurisy with effusion on the left side at the age of seven, and infantile eczema of an annoying condition from the ages of six to nine.

The patient's appetite was variable; at times he was extremely hungry, and at other times he was

FIG. 1.—Diaphragmatic hernia, with colon in left thorax.

FIG. 2.—Showing complete rotation of stomach.

nauseated by the sight of food. He noticed that he could not digest meat, rye bread, and starchy foods. From the ages of fourteen to seventeen he enjoyed good health, though he was always underweight. At the age of seventeen, patient complained of severe constipation, nausea, belching, fatigue after meals, fullness and distress in the stomach, and pain in the lower abdomen. His appetite was poor, and he had headaches localized in the central portion of the head.

Present illness.—The patient dates his present difficulty to five years back when, serving as a salesman, he suddenly became dizzy, and felt sharp pains in the abdomen. Increasing pain in the abdomen necessitated calling a physician. His pain could not be localized. He felt "that the entire abdomen tears to pieces and pulls 'way down, almost to the bladder." From that day the patient had heartburn after each meal, accompanied by nausea and dizziness. He was compelled to use sodium bicarbonate in large doses "to make the belching easier and more frequent." Laxatives did not have any effect upon him, which necessitated the use of strong cathartics. He became alarmed when he noticed a big lump in the lower abdomen which, to him, seemed to be an enormous growth.

Physical examination.—The patient was undernourished, of tall stature and poor posture. The shoulders were bent and the sternum sunken. His height was five feet eight and a half inches, and his weight 122 pounds. The skin was pale, rough, and mottled. The hands and feet were livid and cold to the touch. There were numerous small moles over the right side of the face. Ears, nose and throat were negative. The tongue projected in midline and was much furred. The tonsils were small and injected; thyroid not enlarged; other glands not palpable. Chest expansion was poor, especially over the left side. On percussion, there was marked tympanites on the left side of the chest, especially from the third to the sixth rib. Heart was normal in size and position. On auscultation, many sonorous râles could be heard on left side of the chest, and fine crepitant râles at the end of full inspiration. No murmurs could be detected in the heart sounds. The abdominal wall was sunken, and the muscles of the abdomen flabby. The liver was enlarged and the edges palpable. There were exaggerated peristaltic movements attended with gurgling sounds in the left lumbar region. The ascending colon could not be palpated. The small intestines, upon palpation, presented themselves as a mass. Gaseous fremitus could be easily detected. In the right iliac fossa, there was found a large soft mass which was not painful under pressure. The mass could be moved up or down, with no discomfort to the patient. Upon standing, the mass fell low and more to the right. The abdominal, knee, and arm reflexes were exaggerated.

Laboratory examination.—Specific gravity of urine, 1010; reaction acid; albumen, 3+; phosphate and indican, 4+; other chemical reactions negative; microscopically, hyaline and epithelial cells numerous. Blood pressure 100/60; red blood corpuscles 4,000,000; white blood corpuscles 6,700; differential count of no importance; hemoglobin 75 per cent.; Wassermann negative. The kidney function test shows a fifty per cent. return of the dye in two hours and fifteen minutes. The total secretion of urine during the test period was 1030 c. c. Examination of the stool was of no importance.

Radiographic examination.—The x rays, made by Dr. Maurice Feldman, showed the stomach in right pelvis; completely rotated; pylorus and duodenum to the left; the right abdomen showed an absence of colon and the left diaphragm could not be seen. A colon enema showed the entire colon in the left thorax.

Impression.—Diaphragmatic hernia (left side) with the entire colon in the left thorax; the stomach was completely rotated.

2350 EUTAW PLACE.

Diverticulosis

CHARLES J. DRUECK, M.D.

Chicago

The word "diverticulum" is derived from the Latin *diverto* meaning "to turn aside," and as applied to the digestive tract means a nonneoplastic outpouching of the intestine having a lumen that does or did connect with the bowel. Diverticulitis signifies inflammation of a diverticulum, and peridiverticulitis is an inflammation of the structures surrounding the sac.

Early observers looked upon diverticulosis as a pathological curiosity rather than an important clinical discovery.

In 1710, Chomel (1) reported finding at necropsies pouches or diverticula of the duodenal portion of the bowel. It seems uncertain whether Morgagni (2) in 1762 described true duodenal pouches or some sort of pyloric protrusions which he had found as a cause of death. Fleishman (3) in 1813 reported true duodenal diverticula. In 1853 Virchow (4) pointed out the frequent occurrence of "isolated circumscribed adhesive peritonitis" on the colon, particularly on the hepatic, the splenic and sigmoid flexures. The origin of such local inflammatory changes in the intestinal wall, in its serous covering mesentery, and surroundings he attributed to constipation, thereby sharply differentiating these processes from catarrhal and dysenteric inflammations. Virchow called attention further to possible sequelæ, such as adhesions and contractions, which, for their part, furnish the bases for other groups of symptoms. He was unable to describe the clinical picture of the affections, but believed that many of the cases were misinterpreted as inflammations of the gallbladder and the like.

Rokitansky (5) in 1861 described the condition accurately and Roth (6) in 1872 reported other cases and advanced theories as to the etiology. Windscheid (7) described three cases of acute exudative inflammation involving the entire ascending colon. Herschel and Good (8) in 1880 also added cases, as did Seippel (9) in 1895, Le Tulle (10) in 1898, and Marie (11) in 1899. Hodenpyl (12) in 1900 found the deformity in connection with jejunal diverticula and since then many more cases have been recorded.

Graser (13) was the first to demonstrate the association of acquired diverticula with these pathological processes of the intestine, Bittorf (14) in his contribution on pericolitis attributed extension of infection from surrounding structures; protracted, severe catarrhal and dysenteric affections; intestinal ulcers (tuberculous, syphilitic, typhoid and carcinomatous); constipation and diverticula, the last especially in those cases in which the sigmoid was involved.

In 1911 Buschi (15) made a summary of all the then known cases, fifty-four instances, including three of his own.

This brings us to a period when the röntgen ray investigations began to throw new light on the pathology of diverticulosis in vivo. Bauer (16) in 1912 comments on cases he had observed and attempts to evaluate their clinical significance. Davis (17) reported cases causing death. Baldwin (18), Wilkie (19) and others confirm this. Röntgen ray interpretations now play an important part in most of the reports of this disease, and many illustrated papers have been appearing which prove the frequency of diverticulosis and its relation to other pathological conditions.

Case (20) in 1913 showed four cases in routine röntgen work. Akerlung (21), Linsmayer (22), Rosenthal (23), Secher (24), Spriggs (25) and others have made the subject more interesting by their recent timely papers.

Along with this the problems of operative treatment in diverticulosis has been raised by reports of Forssel (26), Basch (27), Seigert (28), Murchison (29), Lewis (30), and Moore and Ritchie (31).

Diverticula may be congenital or acquired, the former being designated true and the latter false. In true diverticula intestinal tunics constitute the wall, while in false diverticula, one or more coats give way, permitting the mucosa to herniate outward, forming a pouch that may or may not possess a peritoneal covering. Occasionally true diverticula, as a result of prolonged distention, become false, in which case weakened or thinned intestinal musculature shows at the base.

Intestinal diverticula may occur at any age of life, but are comparatively frequent in the middle and especially the late period.

Telling (32) cites 105 cases presenting diverticula, sixty per cent. of which were attended by symptoms. In eighty of Telling's collection the age and sex are given of which fifty-four are males and twenty-six females. Thirty-three cases presented no symptoms which attracted attention to the diverticula and were only incidentally discovered. Forty-seven had symptoms due to diverticula.

Fielder (33) reported a case in a patient aged twenty-two years; Ashhurst (34) reported a case in a patient aged seven years, nine months (operative diagnosis).

Although diverticula may be found in any portion of the digestive tube from the esophagus to the anus, they are rare in the small intestine, occasional in the ileum and cecum and very frequent in the descending colon and sigmoid flexure. Sobel (48) reports a case of gastric diverticulum. They also involve the rectum more often than published cases or postmortem statistics indicate. They are moreover the source of grave pathological processes and sequelæ.

At autopsy, Hansmann (35) demonstrated four

hundred diverticula (small and large intestine) in one case (male aged eighty-five years , death from pneumonia); Curveilhier (36) two hundred, Hodenpyl (37) seventy-nine, and Kivlin (38) over forty, respectively, in a single colon. Treves (39) cites a case in which the entire sigmoid was studded with pouches. McGrath (40) has counted forty-four diverticula from the splenic flexure to the upper rectum.

In the small intestine the diverticula have been observed almost invariably above the mesenteric border, were usually empty, and but one case has been noted in which infection of them gave rise to symptoms (Gordinier and Sampson, 41).

In the large intestine the diverticula have been demonstrated more frequently aside from the mesentery, commonly in relation to the appendices epiploicae, most constantly in the sigmoid and were the source of pathological processes varying in degree from mild to the gravest.

The size of the diverticula varies from microscopic to that of a hen's egg (average size about that of a large pea).

The shape is usually round or ovoid. The smaller, especially were frequently flattened and their long axis transverse, parallel with the bundles of the circular layer of the muscularis. The greater number are sessile; the pedunculated are rather globular in form.

In structure the majority of the advanced diverticula consist of mucosa, submucosa and serosa. Some are composed of all the mural layers. Their openings into the intestinal lumen varies in diameter from nearly that of the diverticula cavity to a diameter much narrower thereby, in the latter case, a stenosis of the exit results.

ETIOLOGY

Opinions vary concerning the etiology and pathology of diverticulosis. In some instances the etiology of the acquired diverticulosis is obvious, but in other cases the causation of the intestinal pouchings cannot be explained except on the basis of inherited weakness of intestinal musculature that gives way owing to gas or fecal distention.

No single factor explains the origin of acquired diverticula in the large intestine, but the process results from a summation of several factors.

1. *Muscular deficiency.*—In the formation of the more common type (socalled false diverticula, hernia mucosæ) are to be seen the same factors which contribute to the production of typical hernia elsewhere in the body, namely, insufficient resistance of the wall, increased pressure from within, the passage of a structure through the wall, forming a *locus minoris resistentiæ,* along which the protrusion makes its course.

That diminished tone of the intestinal musculature may result from general degenerative changes, of advancing age, or debilitating diseases and senility is selfevident. It is very probable that local conditions within the bowel also contribute to the mural weakness. Chronic constipation, complicated by gas and fecal accumulation is an important factor.

Hemorrhagic infarcts, worms, foreign bodies, obesity (with fat intestinal wall), ulcerative colitis, dilated intestinal glands and other conditions have led to the formation of pouches by perforating, destroying or indenting the mucosa, or impairing intestinal musculature.

New growths and various chronic obstructive lesions responsible for obstipation, coprostasis and gas retention are causative factors in diverticula because of accompanying frequent distention, presence of fecal masses and atrophy or thinning of intestinal tunics.

It is also conceivable that congenital muscular insufficiency may be present here as well as elsewhere in the body. The young patients, and those in early middle life, who give no previous history of general debilitating or local intestinal disease, suggest the plausibility of the assumption.

2. *Intraintestinal pressure.*—That the factor of pressure from within is present in the large bowel, is evident from the function of this division of the digestive tube, and, as is well recognized, this force is frequently accentuated by abnormal accumulations of gas and stasis of the intestinal contents, especially in the sigmoid flexure.

Wasting diseases, cancer, tuberculosis, colitis, etc., with intestinal atrophy, favor the formation of diverticula by impairing longitudinal and circular muscle fibres so that they stretch, break or separate, allowing the mucosa to herniate through them when pressure is exerted from within; in such cases normal colonic sacculations sometimes become exaggerated and are mistaken for diverticula.

Mummery (42) emphasizing the pressure theory notes that diverticula are sometimes seen in the bowel wall above a stricture. Such a case was shown at the Royal Society of Medicine in 1919, by Gray Turner. The specimen showed a cancerous stricture of the colon above it. Mummery also reports a case in which a large diverticulum was present in the upper part of the sigmoid above a rectal stricture (carcinoma). He has often observed adhesions which would tend to cause obstruction of the lumen of the colon at the rectosigmoid junction and which appear not to be secondary to the diverticulum.

Normally the tissue surrounding the vessels in their course through the muscular wall is less resistant than the muscular layer itself and it is natural to suppose that its resisting power will also be weakened by the same conditions which affect the musculature. Furthermore, it is conceivable that circulatory disturbances from whatever cause which produce chronic congestion of these vessels with intervals of lowered blood pressure would decrease still more the resistance at these points and thereby facilitate the protrusion of the mucosa.

Klebs has pointed out the anatomical weak points on the mesenteric side of the tube where the blood vessels enter its wall. Herschel found, on distending the bowel, that furrows and even small pouches between the blades of the mesentery pointed to the possibility of false diverticula being produced by intestinal pressure.

Roth reporting five new cases, asserts that they are always of the false type and always on the concave side of the tube. Forster denies that this is universal. Fischer confirms Kleb's statement that small peasized diverticula appear beneath the serosa at the location of blood vessels entering its wall. Grasser and Hansemann also find the foramina, especially of the veins, to be a *locus minoris re-*

sistantiæ in the muscular and fibrous coats. Nevertheless, a few definite cases of congenital origin are reported in which all of the layers of the bowel completely surround the sac. In Linsmayer's collected cases the youngest patient was thirty-six years.

Ages.	*Number of Cases.*
40 to 50	3
50 to 60	5
60 to 70	13
70 to 80	14
80 to 87	4

This would seem to support the view that some degenerative change of the bowel wall is a causal factor.

The other more rare type of acquired diverticula, in which all the mural layers are involved, is probably the effect of a localized weakening of a sacculation together with traction by adhesions from without, or by exaggerated pressure upon this point from within. It is to be noted that congenital diverticula may also occur in the large bowel. The process observed, in which the mucosa tended to bulge outward between separated muscular bundles and appeared independent of the course of the vessels, is very likely due to exceptionally insufficient structure of the muscular layer. This condition may account for some of the infections in which typical diverticula are not demonstrable.

All authors have noted the frequent presence of diverticula in relation to the appendices epiploicæ. Bland Sutton (43) has illustrated by diagrams that this fat is directly continuous with the subserous fat and if there is the slightest tendency to the formation of diverticula it will readily be seen that the soft fatty tissue of the appendix forms a point of lowered resistance.

The observations of McGrath seem to show that this relationship between diverticula and appendices epiploicæ is due to the fact that these fatty masses are points where the larger vessels enter the intestinal wall, since they are the terminations of fat bands, extending from the mesentery and covering these vessels.

Gant (44) in a synopsis of seven cases seen by him reports as follows:

Sex	*Age*	*Variety and Complications*	*No. of Diverticula*	*Location*	*Result*
M	42	Cordlike remains of Meckel's diverticulum (yolk sac).	1	Extended from umbilicus to ileum.	Complete recovery.
F	52	Large pouchings (diverticula) incident to constipation and fecal impaction.	7	Descending colon and sigmoid flexure.	Immediate marked improvement.
M	49	Diverticulum with vesicointestinal fistula.	20	Rectosigmoidal juncture.	Temporary fecal fistula permanent cure.
M	60	Diverticulitis with abscess.	4	Sigmoid flexure.	Recovery in three weeks.
M	47	Diverticulitis with abscess that discharged through the rectum.	1	Rectosigmoidal juncture.	Death from exhaustion three weeks following operation.
F	49	Carcinoma associated with a diverticulum.	1	Sigmoid flexure.	Recovery, death year later from recurrence.
M	63	Diverticulitis of cecum simulating neoplastic tuberculosis.	1	Cecum.	Fecal fistula and death from exhaustion four weeks later.

That these pouches are sometimes congenital is evidenced by the fact that they are sometimes single and sometimes met in association with other anomalies, such as Meckel's diverticulum and esophageal pouches. Wilkie, in particular, has championed the belief that these anomalies of structure are congenital in origin. He has pointed out that the duodenum in the course of normal development gives off hepatic and pancreatic buds, consequently, developmental anomalies might be expected to occur more frequently in this than in other regions of the intestinal tract. The latest observations of Bell (45) furnish good anatomical evidence, however, that many instances of duodenal diverticula are not developmental in origin, although the socalled Meckel's diverticulum, possessing musculature of the intestine, presumably is congenital in character.

In all types sex is evidently a predisposing factor, since the disease occurs more than twice as often in men as in women.

PATHOLOGY

Congenital diverticula are usually found in the small intestine while the acquired diverticula ordinarily involve the cecum, colon and sigmoid flexure. The acquired class is generally considered as independent of development deficiency, but it has been suggested that some of these are, in a certain sense, congenital.

Two types of this class have been recognized: one in which all layers of the intestinal wall are involved, the other in which only some of the layers take part. The most common type of diverticula consists of a protrusion of the mucosa and submucosa, through the muscular layer of the bowel, still covered with the serosa. This form has been described as a hernia mucosæ and well expresses the formative process, which consists of a protrusion of the mucosa through a weak point in the muscularis.

Diverticula vary in size from that of a pea to that of a hen's egg. It may be single or there may be more than a hundred, they may be confined to a single intestinal segment or scattered over several. The form varies from straight pouches with large sufficient openings to those of flask shape, constricted at the neck by the perforated muscular layer, with the bulged out body beneath the serosa.

The pouches may remain healthy or at any time undergo secondary changes (diverticulitis) that may extend to surrounding tissues (peridiverticulitis). Once a diverticulum has formed and feces have found their way into it, the tendency is for it to get gradually larger. The contained feces may vary in consistency from normal to hard concretions. Although the mucosa of some diverticula appears intact, yet as a result of the continued mechanical pressure of hardened fecal material and toxic irritants, the lining epithelium is frequently chronically inflamed in the same manner that stercoral ulceration takes place above a stricture of the rectum. The injury may vary in degree from atrophy to ulceration. Concretions become encapsulated within the diverticula and where the pedicle has sloughed a free foreign body may occur in the abdominal cavity.

Associated with these processes other pathological changes result.

1. As the diverticulum enlarges the walls of the sac are thinned, sometimes to such an extreme degree that only a film of peritoneum separates the diverticula lumen with its fecal contents from the peritoneal cavity. This condition had led to general peritonitis due to osmosis of bacteria or their toxins.

(*To be concluded*)

A Scientific Basis for Therapeutics*

Founded Upon a New Method of Clinical Examination, the Result of Certain Researches of Seymour DeWitt Ludlum and Ellice McDonald

J. MADISON TAYLOR, M.A., M.D.
Philadelphia, Pa.

It has been my privilege to observe the course of certain researches now progressing by Ludlum and McDonald. These have led to a new method or system of examination and have opened up so much of value and proven usefulness in so many phases of disease, impaired nutrition, and predisease conditions that a personal presentation may aid their general appreciation and comprehension.

Their method is essentially the determination of the vagus-sympathetic balance of the vegetative nervous system by means of the smooth or nonstriated muscle as an index and, correlated with this index, the acid-base (hydrogen ion concentration of the blood, P_H) in its bearing upon vegetative nervous system action.

More and more evidence accumulates to show that the vegetative (or involuntary) nervous system controls metabolism and directs such changes in the human body as occur in malnutrition, predisease and disease conditions. Ludlum and McDonald in a preliminary communication (1) have laid down the principles and postulates of their theory without any direct application to special disease conditions.

The vegetative nervous system controls metabolism largely through its power over the involuntary muscles of the body such as in the heart, intestines, lungs, bloodvessels, glands and capillaries. Indeed Glaser—who has done considerable research upon the subject in Berlin—states directly that everything points to the regulatory action of the vegetative nervous system in the metabolism of both organic (sugar, fat, proteins) and inorganic substances.

In the problem of nutrition and metabolism the mineral content bulks large. Indeed deficiencies of one mineral element, or harmful excess of another, lie at the basis of that stable nutritive equilibrium so essential to health and arising in every clinical problem. This is especially significant in protracted, obdurate, chronic, or socalled, incurable diseases and also significant in predisease conditions.

This includes diseases of the body and also of the mind. Diseases of the soma are becoming well appreciated, admirably elaborated and effective. Those of the psyche are vastly more complex, difficult and resistant, being a combination of both.

In these researches, under consideration, the work was begun with the aim of solving certain problems among psychoneurotics, many extreme depressive states, also some involutional melancholias. The work was begun on cases at Ludlum's private sanatorium at Gladwyn for mental diseases, and is being carried on there, and also at Blockley in McDonald's gynecological service. Now it has become enlarged so as to include a variety of internal, metabolic and other diseases and obstinate effects of disease.

The aim has been to explain alterations in vegetative nerve action—vagus-sympathetic balance—and to translate these in terms of the acid-base balance and inorganic salt balance. In short, it is a problem of imbalance, nervous and inorganic, and they have been able to show an association between the two. I availed myself of their aid in a number of grave and obscure disorders and these were remedied beyond all expectation.

This communication is presented to the American Therapeutic Society in the hope of securing constructive criticism. Both the research workers are here today to present their own testimony. This includes a mass of evidence among which are about one hundred direct tracings over the fluoroscopic box giving revelations of altered postural tone of its smooth muscle in the stomach and intestines.

In known diseases and in known conditions as menstruation, definite changes in the postural tone and haustral like (pockets in the terminal colon) arrangement of the large intestine are displayed. These are shown to be dependent upon vagus and sympathetic preponderance in the vegetative nervous system. When experimentally mineral deficiencies are supplied or the excess amounts reduced, the secondary changes in the postural tone are equally characteristic and uniform. It is a study of biochemistry showing fluctuations in rhythm, energy, amplitude and rate in direct proportion to hydrogen ion concentration of the blood.

It was found that when the condition of the blood was more acid (lowered P_H), vagus effects upon the heart, intestines, bloodvessels, capillaries, etc., were found. And that when the blood was more alkaline (higher P_H) morbid sympathetic effects were found. These varied effects could be produced by altering the hydrogen ion concentration of the blood and by administering various salts of potassium, sodium, calcium, magnesium.

The theory is that: all symptoms of disease are dependent upon cell changes and that cell changes are produced by surface action upon the semipermeable cell membrane by the action of various substances (inorganic salts, proteins, lipoids, toxins, antibodies, etc.) which increase or decrease the permeability of the cell, alter viscosity, inhibition, hydration, and potential differences, so producing an alteration in bioelectric variation.

They believe that they can distinguish and appreciate these alterations in the cell by means of the smooth muscle of the body (particularly that of the large intestine) and they correlate this with hydrogen ion concentration (acid-base balance) so delineating the definite condition of the body balance (nervous, inorganic and colloid) in various diseases and laying down a definite scientific basis for therapeutic measures. An example of this is in tetany, where the smooth muscle of intestine is dilated and there is increased P_H (decreated hydrogen ion con-

*Read before the American Therapeutic Society at the Annual Meeting May 23, 1923.

centration, more alkaline) and there is less calcium and more potassium in the blood. In other words it is possible to determine conditions in the human body as in the experimental work of the biologist upon single celled organisms.

In their postulate, they consider the processes of disease to be those in which the basic protoplasmic processes are deranged for whatsoever special reason. Every symptom of disease represents an alteration in the function of cells. Many symptoms are not even accompanied by detectable disturbance in anatomical relationship or noticeable alteration in cellular character.

In medical research and opinion, anatomical relationship holds first place and medical thought has concentrated upon end alterations in cellular character, or anatomical results rather than upon transient cellular changes, i.e., the mechanism of disease. Symptoms must be translated into cell alteration and cellular reactions vary with the tonic content and with the influence of ions upon the protoplasmic semipermeable cell membrane. Energy constant, physiological action is associated with a constant bioelectric variation and, in disease (2), the normal bioelectric variation is upset. They believe that by means of their method of examination, it is possible to estimate the hydrogen ion concentration and the oxidation-reduction poise which is a measure of the bioelectric potential.

Oxidation has come to be considered by the chemists (3) to be nothing more or less than the taking up of electrons, and reduction the giving up of electrons. The production of electric current is thus oxidation-reduction and bioelectric variation depends upon oxidation-reduction in the human body. So that in oxidation-reduction there lies a most fundamental process in the human system. It is believed that this new method will supply an estimate of this process or bioelectric variation through the study of the balance of the vegetative nervous system, the vagus part of which is active in acid oxidation conditions and the sympathetic of which is active in alkaline reduction conditions.

This will exert an immense importance in the choice of drugs and foods. Every drug should be first considered as to whether it is oxidatant or reductant in character and afterwards in regard to its specific or particular effect. This consideration may be obtained by study of the drugs by this method, or by knowledge of the action upon smooth muscle. An example is atropine which is a reducer, dilates smooth muscle and diminishes acidity in the stomach; or quinine which is an oxidizer and stimulates smooth muscle as shown by its action upon the uterine muscle.

In brief: drugs and other therapeutic agents must be considered chemically as to whether they have positive or negative balance. Langmuir has shown that there are three distinct types of valence:

1. Positive valence, the number of electrons an atom can give up.
2. Negative valence, the number of electrons an atom can take up.
3. Covalence, the number of pair of electrons an atom can share with its neighbors.

So that all drugs must be considered as to whether they take up electrons (and are oxidative) or as to whether they give up electrons (and are reductive) because oxidative acid conditions predispose to vagus action, and reductive, alkaline conditions predispose to sympathetic action and these branches of the vegetative nervous system control the action of the heart, lungs, stomach, intestines, glands, kidneys, blood vessels and capillaries, and so control metabolism in all its branches.

In disease also, the acid-base, oxidation-reduction, vagus-sympathetic balance must be considered, because in disease these are deviated from the normal in one way or another. It is of importance to estimate this for two reasons, first to understand the disease processes and second, to apply the correct or complementary therapeutic agent.

Tetany being alkaline, reductant, sympathetic in balance requires calcium, acid, vagus stimulating substances, and so on.

Here according to this theory is a definite, direct, intelligent basis upon which to apply therapy to disease. This can be applied to the action of the endocrines, as for example the reductant, sympathetic, smooth muscle dilating action of adrenalin.

The basis of their method of examination is the then state of smooth muscle as determined by x ray (fluoroscopic) study of the gastrointestinal tract, and the then state of the acid-base conditions of the blood as determined by the P_H determination and the correlation of these to give the acid-base, oxidation-reduction, or vagus-sympathetic balance.

The study also is of importance in determining factors in nutrition and in determining remedial measures as to medication and choice of foods.

Emotional disorders, such as of rage according to physiologists (Cannon *et al*), produce inhibitions of the bowel, heightened blood pressure, sets free sugar in the blood and makes a general adaptation for fight. This is brought about largely through the sympathetic nervous system.

They, Ludlum and McDonald, have found by means of x ray and other procedures that just the opposite situation occurs in anxiety states, a marked acceleration of the bowel peristalsis, a lowered blood pressure and a lowering of blood sugar, a general maladaptation for fight is brought about through acceleration of the vagus nervous system.

These questions arise: why is not immunity merely a mechanism for restoring the proper balance of salts and hydrogen ions in the cell?

Why are not the potential differences in the cell the basis of magnetic flux?

The question of validity of their contentions may be approached from three angles:

1. Vagotonic or sympathicotonic balance can be shown as an essential feature in well being (health), or ill being (disease).
2. Smooth muscle reactions of hollow or tubular viscera can—by their alternation—be shown as original postural balance, and:
3. By a correlation of states of balance with that of hydrogen ion concentration.

The vegetative nervous system controls the heart that beats, the intestines which move, the kidneys which secrete, the complex actions of the liver, etc.

It is obvious that in disease there must be deviation in this state of balance. That is, there is a uniformity in the functional expression of that par-

ticular disease before the organism as a whole can come to rest, or to a mobile equilibrium.

Hence it is obvious that for each particular disease the vegetative nervous system—while controlling the organism as a unit—must then be deviated in predictable directions.

Why do children—undeveloped as to their nervous systems—incur diseases peculiar to their age? Probably because their metabolism has not reached a degree and force of resistance to any depressing action on one or other side, vagal or sympathetic.

Connections between the two nerve systems (constituting postural tone) are made at myriad points, forming convenient interrelationships. The important thing to bear in mind is that they are—in a sense—one way paths; at least in their general relationships between the two systems. All these work outside the voluntary realm.

Hence directive stimuli can only work—plus or minus—to a limited extent as activators or sedators. None the less experience shows that volition—conscious control—can be elicited and does act as a help, at least as a coadjutor.

It also shows how powerful are the effects induced upon the visceral and circulatory functions by induced movements, whereby the centers are stimulated directly. Such action—in my experience—is greatly amplified and elaborated by a combination of induced movements (being handled) and willed movements (performances). Indeed here is supplied an excellent determinable, reliable, convenient, safe and masterful means of enforcing equipoise.

The clinical situation may be described graphically as vagosympathetic imbalance.

The syndrome is exhibited by imbalances occurring in the smooth muscle—postural tone—of the stomach and intestines. Whereas individuals tend to conform to one or other type it may be that under stress or infection, metabolic or other irritation the type phenomena incline toward the opposite.

If so, the facts and causes need to be determined. This these gentlemen are engaged in doing.

Evidences so far point to the situation being one of excessive susceptibility to one or other mineral salt in the blood, or an incapacity to appropriate that which is needful, or in becoming hypersensitive to one other of the ten minerals in the body.

Consentaneously with this deficit being supplied or this excess being removed, many distressing and disabling conditions disappear. In the group under observation (psychopathies) gratifying results have already been obtained.

Polypoid Ulcerative Colitis, Possibly Tuberculous*

GERTRUDE JOHNSON, M.D.

Battle Creek, Mich.

This case is presented as an illustration of what may be accomplished, with Nature's aid, by the internist's patient, persistent efforts to get in harmony with her, even when the patient is almost in *extremis*, and when it is quite clearly evident that the operations thought necessary by the surgeons to relieve what they suspect as the underlying conditions, would cost the patient her life.

Case.—The patient, a girl of nineteen, presented herself for treatment on July 2, 1919. Her chief complaint was diarrhea, accompanied by blood and mucus, which, alternating with short periods of constipation, had persisted for nearly a year. During this time she had lost fifty pounds, nearly half the body weight, and complained of great weakness.

The family and personal history to the beginning of this illness in September, 1918, was negative. The present trouble began with an acute attack of dysentery with daily fifteen or more loose, watery stools containing blood and mucus. The passage of the stool was accompanied by considerable tenesmus. After a few days to a few weeks of such trouble, the bowels would become constipated, with dry hard stools, having the appearance of sheep balls. The patient was confined to bed because of weakness. Her appetite was variable—at times ravenous. She complained of moderate abdominal discomfort, attributed to accumulations of gas; of shooting pains in the head and great weakness.

Physical examination showed a girl fifty-nine and a half inches tall, weight fifty-seven and a quarter pounds; greatly emaciated, skin very pale and dry; tongue coated; whites of eyes pearly, pupils responding normally to light. There was a slight left cervical adenitis. Her heart was normal in size, there was myocardial weakness which seemed to be associated with the general weakness; pulse was 108. There were a few fine crepitations in apex of left lung; liver and spleen of normal size. There was very slight general abdominal tenderness; a slight rupture in the right inguinal region. Pelvic examination revealed a small, slightly retroverted uterus, and a slight erosion of the cervix. The knee reflexes were present. There was a double lateral postural curve. On account of great weakness it was only with difficulty that the patient could stand at all.

Morning temperature was 100° and at 4 p. m. 101.4°. For a period of three months after entrance the temperature varied from 98.6° in the morning

*From the Battle Creek Sanitarium Clinic.

and 99° or 99.4° in the afternoon to 100° in the morning and 101.8° in the afternoon.

The urine analyses showed the presence of a slight trace of indolacetic acid and gave a positive Bergell's reaction; total solids were low, 16.77 grams; ammonia .233; urea 4.16; chlorides 5.58; no albumen or sugar, crystals or casts of any kind.

There were several successive blood tests made on entrance, the lowest point being hemoglobin 20, red cells 1,400,000, white cells 16,500, color index 64. The Wassermann test gave negative findings, and the chemical test of the blood showed a blood sugar of 120. Her alveolar CO_2 tension on July 22nd was 33; another test on August 3rd showed it to be 37. Her blood pressure was 100 systolic and 45 diastolic; pulse ranged from 92 to 108.

Several examinations of warm stools, as well as others, were made, but no Ameba dysenteriæ or other parasites were found. Several examinations were made for tubercle bacilli but none were found; a few streptococci and staphylococci were isolated. The stools were putrid and contained many bacilli putrificus, Bacilli Welchi and Bacilli coli.

A proctoscopic examination showed the mucous membrane, as far as could be observed, covered with hemorrhagic areas. No polypi were observed at this time; later, when the proctoscope could reach a higher point, a few small ones were seen.

Because of the fine crepitations in the extreme apex of the left lung at the back, stereo plates were made. These plates showed a transverse increase especially to the left in the auricular region of the heart. Everything was clear in the left lung except the extreme apex which showed a very slight cloudiness. The right lung showed the base clear, the lung root shadow enlarged with some early infiltration around the ascending bronchi close to the middle line.

Metabolism examinations showed an average pulse of 105, average respiration 11, and a metabolism of plus 10.

A fundus examination of the eyes showed the media clear, both nerve heads swollen, the entire outline being partially obscured, vessels slightly tortuous; there was a double optic neuritis.

By x ray of the gastrointestinal tract, no gallstones were recognized; stomach was normal and emptying time normal; no ileac stasis; ileocecal valve incompetent. There was a great deal of gas throughout the colon during the examination and there was evidence of mucus. The cecum was moderately dilated, its tip lying about even with the brim of the pelvis. The middle of the transverse colon occupied a low position but was movable. The distal colon was spastic throughout. There was a definite filling defect about the middle portion of the pelvic loop that remained permanent throughout the examination. This filling defect involved two or three inches of the colon. There was some tenderness noted in this region and the cecal region was also tender. This filling defect offered some hindrance to the entrance and exit of the barium enema. Emptying time of the colon about thirty hours (Fig. 1).

Because of the x ray evidence of a filling defect in the colon, the question of surgical intervention was considered; in fact the surgeons were very confident that the filling defect was of either a cancerous or tuberculous nature. But on account of the patient's

Fig. 1.—X ray of gastrointestinal tract showing the cecum moderately dilated and a definite filling defect about the middle portion of the pelvic loop, involving two or three inches of the colon.

Fig. 2.—X ray of same patient as Fig. 1, after three months' treatment, showing improvement in calibre of colon. A definite filling defect still existed in the middle portion of the pelvic loop, which offered resistance to entrance and exit of barium enema.

general condition and the fact that she began to show improvement almost at once, it was thought best to postpone operative procedures indefinitely and to go on with medical treatment. I was encouraged to persist in this idea, after two of the first five weeks of slow improvement, by a story told on himself by a famous surgeon visiting our clinic at the time. He told how he had been very much interested in the problem of curing tuberculosis of the kidney. He thought if he could produce a Bier's hyperemia by tying off some of the veins, he might cure it in that way. So he began some experiments on rabbits, inoculating them with tubercle bacilli. After a sufficient length of time he autopsied his controls and found that they had tuberculosis. He was just about to operate and tie off the vein when he became very busy and his mind was diverted from his experiments.

He was unable to get back to the rabbits for several weeks. At the end of that time when his attention was called to the animals by an attendant, he found that instead of dying, as he had expected they would do, they had, under the good food, fresh air and sunshine, quite recovered. He used this as an example to bring to our minds the fact that the only use of physicians anyway is to point out where you are out of harmony with Nature and to assist you in getting back into harmony. And so I went on.

The patient was confined to her bed; was put on a strictly nontoxic dietary, all vegetables and fruits were pureed; was given yolks of eggs and acidophilus buttermilk. She was given no bread or cereals that contained any bran, no sweet milk, whites of eggs or meat. During the first few weeks she was given three dessertspoons of paraffin oil and of agar three times a day, the quantity being reduced gradually to one dessertspoon of each three times a day. She was also given a liquid culture of Bacillus acidophilus and Bacillus bulgaricus, and three fourths of a grain of sodium cacodylate hypodermically every other day for approximately three weeks. She was kept in the open air and sunshine as much as possible; was given light tonic hydrotherapy, such as hot fomentations over the abdomen and back, foot baths, cold mitten frictions, etc. During intervals the Preissnitz compress was used continuously, changing the bandage as often as dry. She was given cleansing enemas of cooked cornstarch made the consistency of thin cream. These enemas were followed at first by a local injection of a paste made of bismuth and petrolatum, and later on a paste of bismuth and paraffin oil was used.

At the end of two weeks her bowels were under much better control, moving less frequently, and she was eating wonderfully well, nothing seemed to disagree with her and she was always hungry and enjoyed her food. She still complained of great weakness, more marked just after the bowels moved; or if she had any gas in the stomach, she would have quite a little distress. In another week her headache had been entirely relieved and she had begun to gain in weight. She was eating at this time about 2700 calories a day. Her bowels were moving much less frequently and the stool was of much better character; the foul odor had disappeared and there was less blood and mucus.

At the end of five weeks her bowels moved only three times during the twenty-four hours. During the week previous she gained two and a half pounds. A proctoscopic examination at this time showed that the slight elevations visible on the mucous membrane of the bowel were disappearing and that the mucous membrane looked much healthier.

By September 8th she had gained fourteen pounds, could now easily walk a considerable distance without fatigue, and was going out driving twice a day. Her appetite continued to improve and she often ate as much as 1100 calories for a single meal and had no trouble in taking care of it. During this time the improvement in her blood count kept pace with the gain in weight and improvement in the intestinal condition, showing a hemoglobin of 40, red cells 2,500,000, white cells 15,000, color index 54.

On September 23rd an acute thrombophlebitis developed in the patient's left leg, which troubled her some for a few weeks but did not seem to interfere with her general improvement.

A reexamination of the colon by barium enema on October 7th (Fig. 2) still showed a definite filling defect in the middle portion of the pelvic loop which offered considerable resistance to the entrance and exit of the barium enema. The rest of the colon was negative with the exception of the cecum, which was moderately dilated.

The patient's temperature gradually became normal about November 1st. On November 16th a blood count showed hemoglobin 75, red cells 3,800,000, white cells 16,000, color index 89. At this time she weighed eighty-two pounds, had a good appetite and normal temperature. On account of the phlebitis which developed in September she was compelled to remain in bed, but by the middle of November was able to walk about without much discomfort.

On December 29th a reexamination of the colon by barium enema still showed a marked filling defect.

By March 1st the patient weighed 101 pounds, was walking on the average of at least two miles a day, and the local condition had continued to improve. The proctologist was frequently able to twist some of the polypi which were lowest down in the colon from their pedicle and both she and the patient reported from time to time small and even occasional large pieces, fleshlike in character, being passed from the bowel. These, unfortunately, were lost before I had a chance to examine them pathologically. The last of March the patient was given leave of absence for six months.

She returned the middle of November, 1920. She had maintained her weight and her general condition was better than when she left. Her hemoglobin was 86, red cells 4,100,000. Her bowels were moving normally three times a day but she was passing small fleshlike fragments from the bowel from time to time.

In June, 1921, she reported for reexamination and observation. She weighed 110 pounds, normal for height. General condition was good. Polypi seemed to be gradually disappearing. She was rechecked in March, 1922, and again in May, 1922, and nothing abnormal could be found in the colon. The patient was weighing around 114 pounds; hemoglobin 96; bowels were moving normally three times a day with no artificial aid. At present she has been carrying on all normal activities for nearly three years.

Differential Counting With the Counting Chamber

A. J. HINKLEMAN,
Oklahoma City, Oklahoma

(*Concluded from page 15.*)

There can be no constancy about the appearance of the large lymphocytes in the blood in increased numbers, except that this will occur when the end of the subject's normal leucocyte response has been reached under stress of the particular infection.

These facts lend strength to the theory of Pappenheim (4) that the large lymphocyte is the mother cell, from which all other cells of the blood are either directly or indirectly derived and that failing leucocyte response, involving either one type of cell or another, is simply a break in the chain of mitosis between mother and daughter cells.

ABSOLUTE INCREASE OF THE LARGE LYMPHOCYTES

In evidence of the foregoing, I have observed the fact that the only time the large lymphocytes tend to decrease below normal absolute numbers is in the early stages of acute infections and when the tendency of the total count is to rise. When this becomes stationary, and especially when the total count tends to fall, while the infection is still active, the large lymphocytes begin to rise. It seems that in the course of the most severe forms of infection and toxic processes there is never a break in the process of leucocyte response involving these cells. In cases of bichloride of mercury poisoning, when the point is reached where all the other cells commonly represented begin to disappear from the blood, the large lymphocytes correspondingly begin to rise. In some cases the large lymphocytes may be equal in number to the polymorphonuclear cells in counts of 20,000, and where the small lymphocytes have fallen as low as from 100 to 500 per c.mm. The same is true of tetanus approaching the fatal stage.

To a lesser extent is this type of a lymphocytosis noticed in such conditions as gangrenous and ruptured appendix, severe abdominal peritonitis, later stages of intestinal obstruction and strangulated hernia, ruptured gallbladder and gastric and intestinal perforation, ruptured ectopic pregnancy, infection of the uterine cavity, threatening eclampsia and uremia, streptococcic septicemia and typhoid fever.

On the side of chronicity, we have such diseases and processes as malignancy, tertiary and latent syphilis, chronic malaria (5), some cases of tuberculosis in advanced stages, and all forms of focal infections (6). The extent of such a lymphocytosis, it must be borne in mind, will be governed, as already has been mentioned, by the severity of the infection, the chronicity of the process and the natural resistance of the individual. In general it can be said that the appearance of the large lymphocytes in increased numbers in the blood is not the best kind of an omen in any kind of an infection; for it means disorganization of the process of normal leucocyte response.

THE EOSINOPHILES

Through the older method of differential counting, little knowledge has ever been gained in placing correctly the eosinophilic cells, either normally or in disease. It is generally classed as one of the cells normally present in the blood, and in such diseases as bronchial asthma, splenomyelogenous leucemia and intestinal parasites, it has a well known clinical significance.

However, from a basis of hematometric differential counting, I have been able to gain much that is new regarding the diagnostic importance of this cell. Being present only in comparatively small numbers in the blood, it has been an easy matter to study it extensively from a basis of from 8,000 to 10,000 cells. I have been firmly impressed, as referred to in my article (7) that the eosinophilis cell is not a normal cell of the blood, in the strict sense of the word. Any cell of the blood that is normally kept up to certain absolute numbers, through physiological chemotaxis, surely has some degree of constancy about its presence in the blood. No such evidences, however, of physiological chemotaxis have I ever been able to detect; but, on the other hand, it has been plain that it is always an evidence of the abnormal, regardless of how insignificant its abnormality may be from a clinical basis. The best that can be said is that it is normally present in the blood only to the extent that minor pathology is normally present in most individuals. I have found it the most important single cell, from a diagnostic viewpoint, especially with reference to the probable location of pathology in the body. What might be termed the socalled normal absolute number of eosinophiles in the blood has been variously placed between 100 and 400 cells per c.mm. I would, however, place this number considerably below this and put it at about 50 per c.mm. and that anything above this must be regarded as being due to some specific extraneous cause.

EOSINOPHILIC POSITIVE AND EOSINOPHILIC NEGATIVE TISSUES

Unlike any other cell of the blood commonly represented, the rise or fall of the absolute number of eosinophiles can be definitely associated with disease or changes within specific tissues, organs or to the action of specific toxines.

Disease of those tissues or organs that have a direct and open connection with the circulation, and in which infection is liable to threaten life directly, uncomplicated, are never associated with an increase of the eosinophilic cells, but rather tend to temporarily remove these cells from the circulation. On the other hand, diseases or inflammatory processes of those organs or tissues of the body in which the route to the circulation is less direct and open, and in which disease and inflammations are always less active and never directly threaten life, invariably are associated with some increase of the number of eosinophiles. A practical classification of the tissues in this respect may be made as follows:

EOSINOPHILIC POSITIVE	EOSINOPHILIC NEGATIVE
Skin	Appendix
Subcutaneous tissues	Intestinal tract
Muscles	Peritoneum
Bones	Pericardium
Urethra	Uterine cavity
Bladder	Liver
Kidneys	Endocardium
Ovaries	Pleura
Male genital organs	Gallbladder
Fallopian tubes	Lungs
Arteries	
Spleen	
Lymphatic glands	
Sympathetic nervous system	

In diseases of the eosinophilic positive tissues, if the increase is not apparent, it will be plain that the eosinophiles are at least not reduced in number. The process of supply will have been sufficient to replace such cells as have been destroyed in the process of inflammation. On the other hand, in diseases of the eosinophilic negative tissues, it will be plain that the eosinophilic cells are taken out of the circulation more rapidly than they are replaced; in consequence of which they will be found markedly reduced or absent in the blood.

DISEASES ASSOCIATED WITH STRIKING EOSINOPHILIA

Most intestinal parasites, bronchial asthma, trichaniasis, splenomyelogenous leucemia, multiple tumors of the skin and disease of the bone marrow. A striking eosinophilia also follows removal of spleen.

DISEASES WITH MODERATE EOSINOPHILIA

Disease of the ovaries, gonorrheal infections, furunculosis and many other diseases of the skin, osteomyelitis, tuberculosis, syphilis involving the arteries, other diseases of arteries, sarcoma and rheumatism.

REDUCTION OR ABSENCE OF EOSINOPHILIC CELLS

Typhoid fever, acute appendicitis, abdominal peritonitis, acute infection of the uterine cavity, infectious endocarditis, bichloride of mercury poisoning, tetanus and severe shock to the nervous system.

EOSINOPHILIC TOXINS

Because of the eosinophilia in connection with certain intestinal parasites and bronchial asthma, it is evident that certain toxins act specifically in the production of eosinophilic cells. Considering the classification of the intestinal tract and the respiratory mechanism under the eosinophilic negative tissues, it must be remembered that it is not the location of the pathology here that has to do with the eosinophilic rise, but rather the specific toxines taken into the circulation. Mechanical irritation to the intestinal tract and the presence of some species of parasites do not produce the characteristic eosinophilia.

In general it can be said about the eosinophilic cells that a marked reduction or absence is not a good omen, but rather points to disease or infection of the more dangerous localities of the body. So long as the eosinophiles are appreciably present in the circulation, the condition may be considered more hopeful as to immediate danger.

What I have thus been able to detect about the eosinophiles with the counting chamber confirms a great part of what has at least been apparent to others who have had to work under a greater handicap, such as the older and more complicated system of differential counting from stained films (8). The foregoing classification of the eosinophilic positive and negative tissues are practically the same as have been set down more indirectly and in a scattered sense by eminent authorities on laboratory methods that are well known at the present time.

SUMMARY

Hematometric differential counting has brought out the following points of diagnostic importance in dealing with diseases and pathological processes most commonly met with in medical practice.

1. A point that permits the classification of diseases and pathological processes associated with an absolute polymorphonuclear leucocytosis.
2. A point that likewise permits the classification of diseases and pathological processes associated with a general leucocytosis.
3. Likewise a point that allows for a classification of conditions associated with a relative polymorphonuclear leucocytosis.
4. Also a point that allows for a classification of conditions associated with an absolute lymphocytosis.
5. A point that allows for the classification of conditions associated with a relative lymphocytosis.
6. A classification of the leucopenias into either an absolute polymorphonuclear or lymphocyte decrease or both and into primary and secondary conditions.
7. A clearer status of the clinical significance of an increase of the large lymphocytes and that such is an omen of failing leucocyte response under stress of severity of infection or chronicity.
8. That the eosinophilic cell is not a normal cell of the blood, in the strict sense of the word, but is present only as a result of the action of extraneous agents upon a certain class of tissues, or the result of the action of specific eosinophilic toxines.

In the articles to follow, certain important diseases and pathological processes, such as the practitioner most frequently has to deal with, will be considered in detail in the light of what a practical application of the principles herein revealed has shown in an extensive series of observations, both in my hospital and laboratory experience, I will try especially to bring out such points as I have found practical in differential diagnosis among groups of diseases that frequently resemble one another clinically, but belong to different classifications with reference to the differential count. Since my aim is simplification, I have made no attempt to distinguish between the large lymphocytes and the mononuclear cells or to deal with such cells as are not commonly met with.

Practical Therapeutics

SOME RECENT EXPERIENCES IN THE TREATMENT OF GONORRHEA*

SAMUEL PARNASS, M.D.
Brooklyn

It is generally agreed that there is no known specific treatment for gonorrhea. Though it is a self limited disease, its duration is often measured in number of years rather than in weeks, because local treatment with germicides often fails to destroy the gonococci hidden in Morgagni's crypts, Littré's glands, the prostate, vesicles, vasa and epididymes. And when a case is complicated by gonorrheal rheumatism the outlook for a cure is far in the future. We are therefore justified in our constant vigil for any new idea or product that promises to be a specific gonococcide. Since our dyes and chemicals that are intended to kill the Neisserian diplococcus directly fail in so large a number of cases, we are not averse to trying vaccines, enzymes and foreign proteins which are likely to increase the body resistance to the invading microörganisms. With these thoughts in mind, I agreed a few months ago to test a certain product, gonolin. I discussed the matter with Dr. H. E. Fraser, who gave me valuable advice and permitted me to test this product clinically at the Kings County Hospital and at the clinic of the Long Island College Hospital.

The preparation is a brown aqueous solution, which is marketed in one c.c. brown colored glass ampoules. It is intended for subcutaneous injections in the treatment of gonorrhea in all its phases. The average dose is one c.c. every two days. The manufacturers say that "it is a combination of protoenzymes that induce active phagocytosis. The enzyme has specific biochemical affinity for the toxin produced by the gonococci, and it neutralizes this toxin. The proteins of the preparation stimulate phagocytosis which carries off the cocci in the following manner: The leucocytes absorb the cocci and transform them into peptones, which are taken up by the erythrocytes and carried to the liver, where the peptones are transformed into aminoacids. The latter are finally eliminated from the system as urates, ammonia and fatty acids."

I have treated a number of patients with the preparation and gave it subcutaneously 689 times, one patient having received forty-four injections. There resulted no local reaction, infection or induration whatsoever, and patients did not object to the treatments. No case of anaphylaxis was met with. A few patients had a temperature of 101 to 103° F, during the first few days of treatment, but in these cases the high temperature was undobutedly caused by the disease (acute epididymitis, rheumatism, vesiculitis).

Among those treated there were twenty-one cases of acute gonorrheal epididymitis. They applied for treatment two to fourteen days aften the onset of the complication, in the average on the sixth day. These patients were kept in bed, ordered to drink much water and to keep their scrota supported with adhesive plaster bridges across their thighs or with some form of suspensory bandage. Each patient received one subcutaneous injection of the preparation in either arm every second day. No other treatment of any description was given—no hot or cold applications, no lotions, ointments, diathermy, narcotics or urinary sedatives and antiseptics. Fourteen patients (sixty-six per cent) were definitely improved in from two to seven days, average five days. By definite improvement I mean the following: entire relief from pain, normal temperature, ability to stand and walk in comfort while scrotum is supported by suspensory bandage, and appreciable reduction in size of inflammatory mass. The other seven patients fared as follows: One who now had relapse of infection of same epididymis was definitely improved in twelve days. One whose epididymitis was also complicated with acute severe vesiculitis, was improved in twelve days. This patient received hot sitz baths three or four times a day for four days for the vesiculitis. Two cases in which there was a marked effusion of serum in their tunicæ vaginalis, giving them the appearance of fair sized hydroceles, took ten and twenty days, respectively, to improve. Two cases of bilateral epididymitis were improved in sixteen and twenty-four days respectively. One patient required surgery: We first saw him six days after onset of epididymitis. It was enormously swollen and was extremely tender; temperature 102° F. After ten days' treatment with the preparation there was no improvement in any symptoms. At operation both the testicle and epididymis were found suppurated and castration was done. Culture showed Baccilus coli and staphylococci. In all cases except in the patient who had orchidectomy, after the initial definite improvement as described, further gradual improvement continued while the treatments were administered every two days. Every patient who continued treatment had only a small nodule in globus minor at end of two months. A few also had slight thickening of body of epididymis. None showed any induration in globus major.

While on the subject of epididymitis, I wish to mention a few facts about its pathology, as gleaned from this limited series of cases: Time of its appearance in relation to the duration of gonorrhea varied from ten days to two years. In eight patients, one third of total observed, it developed in the third week. In one case it developed in the second week. Nine patients had the complication between the fourth and tenth weeks, so that in eighteen patients out of twenty-four (seventy-five per cent) there developed acute epididymitis during the first two months of gonorrheal urethritis. The appearance of epididymitis in the balance of six cases varied from three months to two years. Frequency of occurrence of epididymitis on the left side as compared with the right side: Eleven patients had it on the right side, ten patients on the left side, and three patients on both sides. This finding is at variance with the popular impression that epididy-

*Read before the Brooklyn Urological Society, November 10, 1925.

mitis is more frequent on the left side. Condition of vesicles, ampullæ of vasa and prostate as revealed by palpation rectally: In four out of twenty-two patients (eighteen per cent), the findings were negative. In the remainder (eighty-two per cent) there was definite pathological condition revealed to the examining finger either in the ampullæ, vesicles or prostate, usually on the same side as the inflamed epididymis, but in a few cases both sides were involved in the perivesiculitis and prostatitis. Gonococcus complement fixation test results: In nineteen cases where the test was made, sixteen gave positive result, one was doubtful, and two were negative. The doubtful report was in a case of proved Neisserian infection, and, in view of the rest of the clinical picture, we may include it among the positive cases. One of the negatives was in a case that was clinically a gonorrheal urethritis of nine months' duration, but in which no gonococci were found in two urethral smears, made a week apart. The other negative was in a case of acute urethritis, clinically gonorrhea, of six weeks' duration, with first two glasses of urine cloudy, but in which we were unable to get a drop at the meatus and no smear was examined. There is therefore some doubt as to the causation of the urethritis in the two negative cases, and if we leave them out of consideration, we have practically one hundred per cent positive blood complement fixations in acute epididymitis, a fact worth noting, since many of us are inclined to overlook the value of this test in making diagnosis of gonorrhea.

There were treated eight patients with gonorrheal rheumatism. The gonococcus fixation test gave a positive result in seven patients; the test was not made in the eighth case; we therefore find one hundred per cent positive reactions. Time of development of rheumatism in relation to the duration of gonorrhea was as follows: In seven of the eight cases, it appeared on the seventh to the twenty-fifth day; the fifteenth day was the average. In the eighth patient there developed rheumatism in the fourth month of gonorrhea, and it was mild. All had acute rheumatic polyarthritis. Six of the eight patients had it in moderate form, but of sufficient intensity to cause swelling, redness and pain in joints, inducing patients to take to bed. These six patients received no oral or local treatment, gonolin only being administered every two days. Two patients were free from rheumatic symptoms at the end of two weeks' treatment with the preparation; one patient discontinued his treatment at the end of two weeks when he was much improved as to his rheumatism, although not entirely rid of it; another patient had similar result at the end of three weeks; fifth patient was much improved at the end of three weeks' treatment and was entirely well (as to his rheumatism) in two months; the sixth patient required two months' continuous treatment before he stopped complaining of rheumatism. This patient had moderate hydrarthrosis in both knees, and he had slight stiffness in both knees at the time his treatment was discontinued. The other two of the eight cases of gonorrheal rheumatism were in exceptionally severe form; they were unable to leave their beds and were in constant pain day and night. In addition to the gonolin they were given large doses of salicylates, alkali and narcotics; also hot applications, lead and opium lotion, blistering, etc. At the end of two months, thirty-one injections of the preparation having been administered to each patient, there was no improvement and the treatment was discontinued. Incidentally, I wish to mention that in one of these patients the urethritis, as revealed by the appearance of his urine, had cleared up; in the other patient the urethritis had subsided, but his first glass of urine contained shreds.

EFFECT ON THE URETHRITIS TWO GLASS TEST

There were three acute cases without complications. One of the patients began treatment two days after onset, with first glass of urine cloudy, second glass clear. He received fourteen injections in a period of thirty-five days, when his first glass was still somewhat cloudy, second glass clear. After a rest from treatment for two weeks, both glasses of urine were again cloudy. He did not continue treatment. The second patient with acute urethritis began treatment eight days after onset, when both the first and second glasses were cloudy. He was given a total of thirty injections in a period of sixty days. After twenty-two injections (six weeks), his second glass was clear. At the end of the seventh week he had no urethral discharge and the first glass of urine was only hazy. At the termination of treatment (two months) his first glass of urine was clear but contained shreds. Five days later both glasses of urine were crystal clear, and he was discharged from the hospital. The third case of acute uncomplicated gonorrhea was in a man who had had gonorrhea four years previously, and it then lasted six and one half months. His present infection developed eleven days before gonolin was administered and both glasses were cloudy. He received twenty injections in a period of thirty-eight days, when he discontinued his treatment while his first glass was still cloudy, but his second glass was clear. There was one case of chronic urethritis of nine months' duration. This patient received eleven treatments in a period of twenty days, when his discharge had disappeared and both glasses of urine had become free from pus, mucus and shreds. After one week's rest from treatment, he returned with urethral discharge and both glasses of urine cloudy, a circumstance not surprising in view of the chronicity of the case and the limited number of treatments. One patient with acute gonorrhea, three weeks' duration, plus acute epididymitis, received seventeen treatments in a period of forty-five days, when his urine was entirely free from pus. He was kept under observation for three weeks longer, during which time he was put through the usual tests, and he was then discharged as cured, having only a nodule in tail of epididymis left as a warning for the future. In twelve of the cases of gonorrheal epididymitis or rheumatism described, an average of twenty-three treatments in forty-seven days were given, and at time treatment was discontinued, their first glass of urine was either cloudy, hazy or slightly hazy, while the second glass was clear. One patient, first infection complicated with epididymitis, six weeks' duration, received twenty injections in thirty-eight days, when his urine still contained a little pus (hazy in appearance) in both first and second glasses. In a similar case the patient received twenty-six in-

jections in eight weeks, when his urine had been rendered clear. But he returned two weeks later with both glasses hazy from pus. I gave one patient forty-four injections, and at the end of three months he still had a moderate urethral discharge and slight dysuria. This was his third infection of gonorrhea, and he was finally found to have multiple urethral strictures and chronic prostatitis. In contrast, I wish to cite the following cases: Chronic gonorrhea of two years' duration. Acute right epididymitis, severe, temperature 103° F. His urethral smear was negative for gonococci, but his blood complement fixation for gonococcus was positive. He received thirteen injections in a period of thirty-two days, and his urine became entirely free from pus. Ten days later, after instrumentation in test for stricture, urethral discharge reappeared, but no gonococci were found in the smear. No further treatment was given, and this case was entirely cured, at the end of ten weeks from the beginning of treatment. Another patient, after twenty-eight injections, had only shreds in first glass of urine, and five days later, after the administration of two more treatments, his urine was clear. Still another patient had his urine crystal clear after thirty-one treatments.

This report contains all the facts about gonolin as far as I know them. My findings are unbiased. It would be interesting to know what results would be obtained if much larger doses were given. As already stated, one c.c. doses have produced no local or systemic reactions, and I feel sure that much larger doses, two to four or five c.c. would be safe to administer every two days. It is possible that this more intensive treatment would bring quicker and more satisfactory results. For the present, considering this a preliminary report, I wish to emphasize the good results obtained in almost all the cases of gonorrheal epididymitis and in seventy-five per cent of the acute gonorrheal polyarthritis cases that received no treatment except gonolin.

SUMMARY

There were twenty-one cases of acute gonorrheal epididymitis. Fourteen of these patients (sixty-seven per cent) were definitely improved in five days average. Six patients were definitely improved in from ten to twenty days. One patient was not helped, and needed surgical interference.

There were eight cases of acute gonorrheal rheumatism; two of these patients were cured in two weeks; one patient was much improved in two weeks; one patient was much improved in three weeks; two patients were cured in two months; two patients were not benefited at all after two months' persistent treatment.

In gonorrheal urethritis the treatment with gonolin did not give the results hoped for, and I thought that we might have gotten better results if larger doses had been given. In only five cases out of a total of twenty-three did I succeed in obtaining a pus free urine at the end of treatment. In the other eighteen cases, there was still some pus in either the first glass of urine or in both the first and second glasses of urine at the time treatment with gonolin was discontinued.

1164 Dean Street.

Mode of Action of Diathermy in Chronic Urethritis.—E. Roucayrol and J. L. Angulo (*Paris médical,* August 8, 1925) adduce evidence to show that diathermy does not act in these cases directly through the effects of heat on the gonococci, but through the production, in the presence of gonococcal toxin, of a marked influx of young and active polymorphonuclear leucocytes which ingest and destroy the germs. If diathermic treatments are continued after disappearance of the gonococci, the phagocytes are no longer present. Before diathermy, smears show only a few, old polynuclears, which have no phagocytic power. Diathermy sets free the gonotoxin, and the heavy influx of young phagocytes can be seen microscopically to ingest the toxin free bacteria. That the heat does not kill the germs directly is indicated by the fact that the staphylococcus, a germ which resists high temperatures, disappears likewise under diathermy. Treatment of chronic gonorrhea with diathermy should be kept up as long as gonococci and discharges of polynuclears are seen in serial smears. When gonococci persist but discharges of polynuclears no longer appear under diathermy, the latter should be discontinued, and later resumed if the gonococci (now free of toxin) are not eliminated by the natural defensive processes. Complete cure can always be obtained ultimately, provided the diathermy is applied in a scientific manner and combined with dilatation. Where discharges of polynuclears are sent to continue in spite of the apparent absence of all germs, the treatment should be kept up, as these discharges prove that germs are actually present, since fresh amounts of stimulating toxins are being set free. Diathermy also possesses, however, the property of bringing deeply situated germs to the surface of the mucous membrane, and for this reason affords an excellent means of diagnosis.

Interscapulothoracic Amputation.—C. Wallace (*British Journal of Surgery,* July, 1925) records the following method of incision for carcinoma of the breast, as one providing sufficient covering for the raw surface left after wide removal. The incision started over the sternomastoid, about three inches above the clavicle, passed down to and over the sternoclavicular articulation; it then turned outwards two inches below the clavicle, crossed about two inches above the angle formed by the junction of the skin of the chest and the arm; then across the deltoid, sloping slightly downwards to the point where the posterior aspect of the arm joined the body; then backwards and downwards almost to the angle of the scapula. From this point it turned forwards, crossed the axilla horizontally below the border of the mamma, and reached the sternal edge, which it followed to the sternoclavicular articulation. By turning the superior flap upwards, it was quite easy to divide the muscles on the superior and vertical border of the scapula and turn forwards the upper extremity and detach it from the thorax. The continuation of this process enabled the arm, scapula, pectoral muscles, and mamma to be removed in one block. The shock was no greater than that encountered in many breast operations. In each case a small part of the anterior edge of the skinflap necrosed, but otherwise the flaps healed well.

The Normal Infant and Child*

H. BROOKER MILLS, M.D., F.A.C.P.

Philadelphia

Almost everything that is said at the present time, both over the radio, in person and in lectures, as well as most of what is written these days about babies and children, pertains to the illnesses from which they suffer and their methods of prevention and treatment. It has seemed to me that if parents knew more about the points that go to make up a normal infant or child, they would not only be spared much anxiety about their own and much envy of their neighbors, but would also be in a much better position to determine whether or not their own were as abnormal as they have been led to believe, when their only guide was comparison with others.

The average weight for the normal baby at birth is seven pounds, and this should be doubled in six months, and trebled at one year, so that when mothers, by comparing their infants with others, feel they are very much underweight, they do not realize that such may not be the case at all; rather the opposite being true, that the other baby is very much overweight, and is, for many reasons, rather to be pitied than congratulated. Few mothers know that the birthweight has so much to do in deciding the average normal weight at six months and at one year, while practically all mothers know that proprietary and patent foods are great weight producers. In spite of this, when comparing the weight of their babies with other babies, they do not stop to inquire the other babies' birthweight, nor whether the other babies were breast fed or bottle fed, and, if bottle fed, whether they were on the great weight producing foods, or on the foods that produce length and strength, increased resistance to disease, increased vitality to help them in convalescing from diseases, better shaped heads, straighter and stronger legs and spines, etc., which conditions are only brought about by the use of either human milk or cow's milk. When cow's milk is used it should always be either certified or pasteurized, and never the milk from one cow, but always from a herd of cows.

All babies should, and most babies can, be raised on human milk, certainly many more can than are, and the next best food for infants is cow's milk properly diluted to meet the needs of the particular patient. While cow's milk is intended for calves and not human beings, it is far superior to proprietary and patent foods in that, while it does not produce the fat baby so desired by the average mother today, it likewise does not produce the cases of rickets and scurvy that so commonly develop on proprietary and patent foods.

In the case of a breast fed baby fruit juices should be started at the fifth month, while in a baby on a bottle they should be started at the third month, thus supplying the mineral salts so necessary for the baby's future welfare, and which are not present in proprietary and patent foods at all, nor in cow's milk to the extent needed, when one considers this milk has to be diluted to meet the requirements of the individual patient.

Mothers frequently ask at what age the bottle should be stopped in the case of a bottle fed baby, and my answer is one year from the time the bottle was started, so that, if a baby was on the breast for six months, and then the bottle was started, it should be stopped at the age of one year and six months, and so on. I believe the use of a bottle for more than one year from the time of starting is one of the three most common causes of enlarged adenoids and tonsils in young children, the other two being thumb sucking and whooping cough.

Another question of importance is the age at which the breast fed baby should be weaned, and also the age at which solid food should be commenced in both a breast fed and bottle fed baby. As to weaning, this should be started at the ninth month by giving a bottle a day, and the next three months, i. e., until the baby is one year old, more and more bottle feedings should be given and less and less breast feedings until, by the time the age of one year is reached, the baby is entirely on the bottle, and entirely off the breast. At this time, i. e., the age of one year, solid food should be started to alternate with the bottle, more and more food, and less and less milk from a bottle being gradually given until at the age of one year and nine months the bottle is stopped entirely. From the fifteenth month on the baby should be en-

*Broadcast from Station WLIT July 14, and August 25, 1925, at the request of the Director of the Department of Public Health of Philadelphia, and read before the Hazleton Branch of the Luzerne Co. Medical Society of Pennsylvania, on September 24, 1925.

couraged to drink its milk from a cup or glass so that the stopping of the bottle becomes not only an easy matter, but may even be accomplished much earlier than one year and nine months if desired. When it comes to the bottle fed baby, solid food should be started at the ninth month, after which the same procedure should be followed as in the case of the breast fed baby, i. e., more and more food and less and less milk from a bottle being gradually given, until the year is up from the time feeding from the bottle was started, at which time the baby should be entirely on table food.

Parents could learn much from their infants in reference to the taking of nourishment during the warm summer months. While the average adult will drink large quantities of liquids on hot days, only to perspire more freely and feel the heat more intensely as a result, a bottle fed baby will usually refuse a part of the contents of each bottle, much to the baby's credit and comfort, although greatly to the anxiety of the mother.

Another question asked is in reference to preventing the forming, and, when present, the getting rid of gas in the stomach which frequently accompanies and follows feedings, particularly in bottle fed babies. Much can be done to prevent the formation of gas by gently rubbing the infant's back while taking the bottle, and seeing to it that the infant lies on its right side during this time, with its head and shoulders slightly elevated at about the angle it would occupy were it in the mother's arms taking the breast, while, if the gas does form anyway, placing the infant over the mother's shoulder and gently rubbing the back at the same time will usually expel the gas without any trouble. It is sometimes wise for the mother to put the infant over her shoulder before commencing the feeding, and again when part way through, as well as after finishing, and frequently the doing of this before and during the feeding will prevent the necessity of having to do so after finishing, which is a distinct advantage, as it lessens the likelihood of causing vomiting, and obviates waking the infant, if sleeping.

While speaking of vomiting, I would call parents' attention to the fact that by vomiting we physicians mean the return of food that has been in the stomach long enough to become curdled, so that when it comes back it is very thick, looking somewhat like cottage cheese, and has a sour odor. Simply spitting up a little watery fluid soon after finishing a meal is referred to by physicians as regurgitation, and it is important for mothers to learn the difference in the meaning of these two terms, as vomiting almost always requires medical attention to learn the reason why, and remove the cause, while regurgitation frequently acts like a safety valve, getting rid of food that, were it retained, would often cause considerable pain; in other words, regurgitation is frequently the result of taking too much food, taking the food too fast, or the formation of gas before or during the taking, and therefore the prompt return of a small part is a great benefit to the baby, whereas vomiting is rarely from any of these conditions, but is much more likely to be an evidence of improper food, proper food improperly prepared or given, some digestive disturbance, frequently constipation, or the onset of some illness. Concerning the proper preparation and giving of the bottle I would call attention to the fact that I believe it is much better to prepare the food at the time of giving each bottle rather than in the morning for the entire day, especially in summer time, and I am convinced that the holding of the bottle until its contents have all been taken, or at least as much as the baby needs, is one of the most important points in the artificial feeding of infants, and one of the best methods of preventing digestive disturbances. To prop up the end of the bottle on a towel or napkin and go away and leave it, thus shooting the food into the stomach much as the coal is shot into one's cellar, is radically wrong, as the neck of the bottle cannot be kept constantly filled as it should, thus preventing the sucking of air; the regulation of the rapidity with which the contents of the bottle is taken, while valuable, is impossible, and one does not know whether or not the bottle has rolled away and the baby gone to sleep after only a part of its contents has been taken, which would mean it would be awake and hungry before the next feeding time was due. Removing the bottle two or three times during a feeding in order to lessen the rapidity of taking has much to do with the prevention of the formation of gas, and also the regurgitation, or vomiting, or both that may follow, and naturally this is not done if the bottle is left for the baby to take by itself, instead of being held as it should.

Considerable difference of opinion exists as to whether or not a baby should be awakened at feeding time, and, while I realize such should be done if one desires to raise an infant like a machine, i. e., to eat at regular intervals, awake or asleep, need it or not, I personally am not in favor of this being done. I do not believe a hungry baby, or one in pain, will stay asleep; at the same time, I do not believe a baby that is not hungry and not in pain is either going to awaken voluntarily by the clock, nor should it be compelled to do so. As proof of the truth of this I would mention the statement frequently made to me by mothers, that their babies always have a long sleep after the morning bath. This is no doubt in part due to their being tired, but that would not stop them from awakening on schedule time if they were hungry or in pain. One of my principal objections to awakening the sleeping infant in order to feed it is that frequently it is too sleepy to take more than a part of the feeding, and even that only by coaxing, which means it is going to be awake and hungry before the next feeding is due, to say nothing of the fact that food taken only by coaxing and urging is frequently regurgitated, or vomited, or causes some digestive disturbance. I am in favor, therefore, of having a minimum interval between feedings, but no maximum, in other words, decide for the mother how close the feedings may be given, which depends on the age of the patient and the quantity of food in the bottle, and let the baby decide how much further apart the feedings may be, depending upon the time when hunger will awaken it.

To avoid waking the baby up or causing vomiting, or both, it is better that a bottle fed baby should be given the bottle where it is going to do its sleeping after taking the bottle, especially as, when mothers give the bottle with the babies on their laps, they almost always sit in a rocking chair to do so.

Plenty of water should be given to babies, whether breast or bottle fed, between feedings, and most of

their sleeping should be done lying on the abdomen rather than on the back.

Having discussed what the normal baby should weigh, and how the normal baby should be fed, a word might be said as to how the normal baby should be clothed, especially at this time of the year. Just as it is true that more babies cry and suffer from overfeeding than underfeeding, so more cry and suffer from being overclothed than underclothed. Why does not the average mother apply the same principle to the clothing of her baby as she does to herself, which is to put on as little as the law allows, or only as much as the law compels? The baby has just the same right, and probably even greater need, to be scantily clothed as the mother, and, while we could not expect the mother to go bareheaded and barefooted, although I am sure she would do so were it the style, the baby surely should, at least during the summer months.

The average baby should be able to support its own head at four months; sit erect at seven months; stand at ten months; walk with help at one year, and alone at fifteen months. The training of all babies in the use of a chair for bowel movements should be commenced at the third month, so that they should be thoroughly broken to its use by the age of one year. This is not only important from the viewpoint of being a great advantage to the mother, but also means that the baby should at this time be prepared to discard diapers, as the restriction that is caused by diapers in the free movement of the legs in walking undoubtedly favors the development of bow legs even if not of curvature of the spine.

All babies should be vaccinated by the fifth month, in other words, before there is much likelihood of teething beginning, this usually starting in a breast fed baby between the sixth and eighth month, and in a bottle fed baby generally somewhat later, although this is the most variable function of infancy, some being born with teeth, and others not having any until nearly or quite a year old.

Speaking of teething, it is not unusual to hear mothers object to devoting time and money, and perhaps causing a little pain, in the care of children's first teeth, they taking the point of view that, as they are only temporary anyway, there is nothing to be gained by it, whereas, as a matter of fact, the same care should be given the first teeth as the second. One reason for this is keeping the mouth healthy and enabling the proper chewing of the food taken, and a second reason is that the less time that elapses between the shedding of the first teeth and the cutting of the second, the easier will be the cutting of the second, and the more regular will the second set be.

All infants should be given, between their sixth and ninth months, the three injections necessary to protect them from diphtheria, and, in the near future, it is hoped by the medical profession to be in a position to recommend similar treatment for the protection against scarlet fever.

As to children of preschool age, perhaps few things are more important than their environment and their companionship, and, for this reason, an only child, like a fat baby, is to be pitied. The children of preschool age should be encouraged to give free vent to their love of play, especially outdoors, and surely should not be taken to see exciting moving pictures, or allowed to become unduly excited, whether from play or otherwise, between the time of the evening meal and the time of going to bed. The more time they spend with other children and the less time in the company of adults, including the parents, the better.

I wish to sound a note of warning to parents concerning children of school age, and that is that, with the school work and hours as exacting as they are today, I do not believe a child should be encouraged, or even permitted to take up any other studies, such as vocal or instrumental music, etc., at least until high school age is reached, even if then, many of the nervous affections which we have to deal with today in children being, in my judgment, due either to their being allowed to take up some other study because they like it, or encouraged to do so by the parents as a matter of parental pride when their children are compared with others. All hours not needed for school work should be spent out doors, and even the home work from school should be reduced to a minimum, and not done just before the child is to retire for the night.

I would like to say a few words in reference to the value of play for the child of preschool age, and also of school age, not only to the child but also to the parents, especially the mothers. Take a mother of several children, with her multitude of household duties to perform, and think of what a saving of time it would be to her if her children had been taught organized play, and given full freedom to enjoy and practise it. The laughter of children at play is the sweetest of music to the mother's ears, to say nothing of the peace of mind and freedom of action that play on the part of her children would afford her.

Emerson, in *Nutrition and Growth in Children,* says: "There is wonderful training for the powers of the growing child in play. Free play is constructive, and calls into operation the various mental and physical capacities. Children should be encouraged to work out their games in their own way without too close or too constant supervision by adults. In this way they learn to discipline themselves and one another. During the early years interest centres in imitating the activities of older persons, but at the age of seven or eight the spirit of competition develops, and foundations are laid for association and team play.

"In the World War it was shown that the strategy worked out in games was adapted to the serious purpose of war maneuvres. The play of the boy became the work of the man, and some of the best achievements were made by young athletes of trained eye and muscle but with no previous military experience.

"Nothing is more pathetic than the child who has never learned to play. Many of the nervous breakdowns of later life occur because men and women who failed to form the habit of play in childhood pursue their work intensely without recognizing the need for adequate recreation and exercise. The habit of play is a permanent safeguard to health."

Rachford, in *Diseases of Children,* says: "In the modern well appointed home the child too often has some one to do his thinking, some one to minister to his every want and some one to teach or amuse him throughout his waking hours. He has little time to himself and a very small portion of his day is

spent in play with his intellectual equals. Where these conditions exist there is little chance that the best possibilities in the boy will be utilized for making the best possible man." In 1893 I wrote as follows: "If there is one crying evil common to all of our large cities, it is the scarcity of playgrounds for children, and the attention of humanitarians should be called to this fact. If our generous citizens would pause long enough in the building of hospitals, libraries and places of learning to realize there is a field almost totally neglected by the humanitarian and one of quite as much importance to the welfare of our communities, then possibly a portion of the vast sums of money annually spent in this way would be used in providing playgrounds for children. These playgrounds should not be covered with beautiful grass plots guarded by policemen, but they should be playgrounds in the best sense of the word; places where ball, tennis and all kinds of healthful sport could be enjoyed." Since these words were written much has been done in our large cities to furnish playgrounds for children, and a movement is now apparently spreading over the country, hand in hand with the fresh air movement, which is teaching the poor as well as the rich that healthful play in the open air for a portion of the day and healthful sleep in fresh flowing air at night are much more important to the success of the future man and woman than is the number of hours spent in the schoolroom. The day has apparently dawned when the physiological importance of the physical as well as the mental development of children is to be generally recognized, and cities and philanthropical societies will be called upon to furnish like opportunities for the development of both.

Another point on which I have been asked to express an opinion is that of "sparing the rod and spoiling the child," but I hesitate to do this because I feel that the way to correct a well child is exactly the same as the way to treat a sick one, i. e., as an individual, and not as one of many. Just as a physician would not think of treating all sick children the same way, even although suffering with the same disease, so a parent could not and should not be expected to correct a child the same way any other child was corrected, even although what it had done to need correction was just the same thing as the other child had done, because the two children would probably be so entirely different, especially in temperament, that what would be a warning to one not to repeat would be a stimulant to another to do it over again. Of one thing, however, I am quite sure, and that is that whipping is far better than frightening or threatening, such as putting the child in a dark room, or threatening to punish sometime later, instead of doing it right then, or not at all. The following are some of the expressions used by mothers to control their children: "Be good or the doctor will cut your tongue out." "The old man with a black bag picks up little girls who don't mind their mothers." "Steal more jam and I'll whistle for the green eared bogey man in the hall closet." Depriving children of something of which they are fond, particularly some form of pleasure, is one of the safest and best ways to punish, and another good way is to deprive them of something which they like very much to eat, but never of an entire meal, particularly on retiring. After all, to control by love rather than by fear is the ideal method to employ. Many mothers would have much less need to correct their children, and, when necessary, be much more successful in doing it if left to themselves to decide the means to be employed; in other words, it is usually the interference on the part of others, especially well meaning but misguided friends and in-laws, that makes it difficult for many a mother to raise her child properly, and to correct and punish it when necessary in the way that is going to do the most good. More than one mother has expressed to me the fear that she was responsible for some nervous condition from which her child was suffering owing to her having so frequently threatened all kinds of terrible things when the child had transgressed a little from the normal, many of these transgressions being due to the many hours the child was compelled to spend in adult company, when it should have been outdoors playing with other children.

If there are any dont's that I would like to impress upon parents, they would be the three recently used by Dr. I. A. Thom as follows: 1. "Don't bribe." 2. "Don't make promises which you know you cannot or do not intend to keep." 3. "Don't threaten a child in order to obtain control over him." Many parents are very proud of the socalled brightness of their children, especially in the case of an only child, when as a matter of fact it is not brightness at all, but simply an example of the little old man and little old woman ideas the children have gotten from their adult rather than childhood association. In such cases the children are to be pitied, rather than praised or complimented, as they have really had no actual child life at all, the sweetest years of their existence having been spent in mental development, frequently at the expense of the physical, with none of the joys and sweetness of child life to compensate for it. A child is as old as its behavior. By the age of two years in many children the sense of dignity is well developed, and their feelings at this age can be readily hurt by ridicule. It might be well to remind you that between the ages of two years and six years children make their most marked mental and physical development, which is one of the great reasons why the proper training during these years is all important.

While I would be the last one to say a word against education for all children, I am quite sure that many children are compelled to go through high school, and even college, that are neither mentally or physically fitted for such a strain, and would do far better in some line of business where perhaps such advanced education was not required, but for which they would be much better adapted. Of what use is a fine education to mental and physical wrecks, who would probably not only never be able to make use of the education, but frequently will have been so harmed during the time spent in its acquirement that they are not fitted for the active strain of a business or professional life for which they have been so carefully and thoroughly prepared.

This leads me to the last point in my talk, which is the question of whether or not parents should endeavor to influence their children in selecting the kind of work the children most desire to make their vocation in life, and I am quite sure that young men

and young women who have made their own uninfluenced selection do better than those who take up some line of work in which they have no interest and for which they have no natural gift, because of parental influence. Many a father feels his son should follow in his footsteps, and be prepared to take over the ready made business at his father's death, but, unless the young man is so inclined naturally, he will not only do better to follow his own inclinations, but will also make a greater success, and the world will be the better for his having lived in it if he made his own way instead of sitting back and enjoying the fruits of the parent's labors, which meant nothing to him.

You, the unseen audience, may have noted I have referred almost exclusively to mothers, and I do so because it is largely up to them as to whether an infant or child is normal or abnormal. Of course, this should not be, and I hope any fathers who may have been listening in will take the hint to assume more of the responsibility of the bringing up of their offspring in the future than many, if not most, of them have done in the past.

If any of those who have listened to this short talk have learned anything about what goes to make up a normal infant or child, and, equally important, anything about the things to do, and not to do, to keep the normal infant and child from becoming abnormal, your time and mine will have been well spent.

Massive Atelectasis (Massive Collapse) of the Lung

With Report of a Case Occurring in an Infant of Three Weeks

J. P. CROZER GRIFFITH, M.D.
Philadelphia

Much interest has of recent years arisen in regard to massive collapse of the lung, as it was named by Pasteur, who first directed attention to it in 1890 (1). It is believed to be a special form of extensive, localized atelectasis, brought on by special conditions. Whether, however, it is to be regarded as a clinical entity, different from other forms of atelectasis, seems to be a matter open to difference of opinion. The object of what follows is, first, to report a case of what appears to be massive atelectasis, interesting on account of the very youthful age of the patient and the peculiar manner in which the collapse probably was produced. Second, to point out the possibility that similar physical signs, as shown by auscultation, percussion and x ray examination, can perhaps be produced in other ways than by the occurrence of this complete collapse.

The case in point is as follows:

Case.—Marie R., born July 21, 1923, about two weeks prematurely. Weight at birth five pounds. There was no asphyxia or cyanosis following the delivery, which was a perfectly normal and easy one. Artificial feeding became necessary soon after birth. I saw her in consultation with Dr. Harry L. Rogers, of Riverton, N. J., on August 7th, on account of loss of weight, diarrhea, rather frequent vomiting, and a decided tendency for the food to be regurgitated through the nose while taking the bottle. There had been no fever and the examination of the lungs had given negative results.

Examination showed a fairly well developed child, weighing four pounds four ounces, but without depression of the fontanelle or any evidence of dehydration, cyanosis or marked debility. Under regulation of the diet the baby improved rapidly and gained a pound in a little less than a week. On August 12th she was admitted to a private room in the Children's Hospital of Philadelphia to be studied for the difficulty in swallowing referred to. There had been no fever or any evidence of pulmonary involvement, and examination of the lungs had shown nothing up to this date.

Physical examination on the day following admission gave surprising results, in that there was discovered impaired percussion resonance over the right side, with distant breath sounds, especially at the base, and a few moist râles. On August 14th there were loud bronchial respiration and bronchophony and numerous fine râles over the whole affected side. Since the12th there had been a trifling cough; the cry had been fair; occasionally there was a slight duskiness, but as a rule the color was good. X ray examination was made on August 14th with the following results: Left lung practically clear; dense shadow throughout the entire right lung, shadow of heart entirely on the right side; a high stand of the diaphragm (Fig. 1).

The child continued to improve rapidly. There were no symptoms whatever indicating trouble with the lung. Regurgitation ceased in a couple of days. Physical examination on the 15th showed lessening in the intensity of the signs, and x ray examination on the 18th diminution in the shadow but with the heart still to the right. By August 20th auscultation and percussion failed to demonstrate any consolidation and the x ray showed the heart and diaphragm returning to the normal position (Fig. 2). The baby was taken home August 21st in excellent shape. While in the hospital she had gained weight rapidly; the temperature had ranged from 97° to 98.8°; the pulse from 118 to 126; and the respiration from 24 to 64 but usually from 34 to 52; that is to say, all three were entirely within normal limits. Letters received one month and two months later reported continued good condition and rapid and steady gain in weight.

The principal features of this case may be summarized as follows: A slightly premature baby, two weeks old, exhibited some indigestion, but no other symptoms except a decided tendency to regurgitation

of food through the nose while taking the bottle. Gained one pound in about a week. Then, without change in symptoms, exhibited extensive consolidation on the right side, with displacement of the heart to, and a high stand of the diaphragm, on this side. There was no alteration of temperature, pulse or respiration, and the general condition improved steadily. About a week later all auscultatory and percussive signs of consolidation had disappeared, and the x ray showed heart returning to normal position. Entire absence of any pulmonary symptoms throughout the disease.

In considering the relationship of this case attention must first be given to the possible existence of ordinary atelectasis of the newborn. Briefly detailed, this is a condition developing in feeble infants; is practically always bilateral, although one lung, usually the left, may be involved more than the other; affects especially the frontal or paravertebral region and particularly the lower lobes, and is patchy in character rather than dense and uniform. The symptoms consist of marked prostration, rapid and feeble pulse, shallow rapid respiration, and dyspnea. The physical signs are usually dullness upon percussion, feeble respiratory murmur and moist râles.

The case here reported had practically nothing in common with this description except the occurrence of prematurity; this being apparently without influence, as indicated by the fact that the infant was rapidly improving at the time the local condition was discovered. Further, the physical signs were those more characteristic of pneumonia, the respiration was in no way affected, the x ray indicated more consolidation than is the rule in ordinary atelectasis, and the disorder was limited to one side. The atelectasis must have been of recent development since examination of the lungs made before the child came to the hospital had revealed nothing abnormal.

Next in order comes the consideration of the so-called massive atelectasis or massive collapse of the lung. All of Pasteur's fifteen cases of his first report occurred in children, and all of them were instances of diphtheritic paralysis in which the muscles of respiration, including the diaphragm, were more or less involved. In all of them there was an accompanying paralysis of the palate and pharynx, and tube feeding was frequently necessary on account of the difficulty in swallowing and the leakage of food into the air passages. It is to be especially noted that in at least one of the two autopsies reported by him in his first publication, there was not only extensive atelectasis of both lungs but evidences of bronchopneumonia as well. In later publications (2) Pasteur extends his discussion to include postoperative collapse. He defines massive collapse as a sudden, complete collapse of a large area of pulmonary tissue, and says it is to be sharply distinguished from the partial form. He thinks that it is always dependent upon a failure of respiratory power, and questions whether obstruction by viscid mucus can ever be a cause. Other observers believe strongly in the influence of obstruction.

Too much has been written upon the subject to allow of any extensive discussion of it at this time, and the reader may be referred to the useful reviews by Abt (3) in reporting a case of a boy of fourteen years, Lee (4) who published the details of five cases, in which the youngest patient was fourteen years old, and Scott (5) who gives an exhaustive review of the subject as seen in postoperative cases.

As Lee points out, the various causes which have been assigned may be placed in two groups: first, those which produce interference with the respiratory movements, and second, those which bring about ob-

Fig. 1

Fig. 2

Fig. 1.—Showing solidification of the right lung, with decreased displacement of the heart to the right and high stand of the diaphragm on this side.

Fig. 2.—Showing disappearance of this collapse and a return of the heart and diaphragm to the normal position.

struction somewhere in the bronchial tree. In the first category is to be placed the action of the diphtheritic paralysis of the respiratory muscles, and the performance of surgical operations especially upon the abdomen. In just what manner such operations occasion collapse has received numerous explanations which are not entirely in accord. It may be concluded, however, that the process is one which, in certain cases at least, in some way limits the respiratory movements. Thus, penetrating wounds of the thoracic wall may be followed by collapse, and this is quite understandable, as is the action of diaphragmatic pleurisy.

Obstruction of the bronchial tree in any part is naturally followed by collapse of the portion of the lung reached by the blocked tubes. Not only may a foreign body produce such an obstruction, but an accumulation of mucus may have exactly similar results. Lee strongly emphasizes this, based upon actual demonstration; and bronchoscopic work has proved its truth. Probably pneumonia, particularly the catarrhal variety, may produce atelectasis as a complication through the closure of certain of the small bronchial tubes. Certainly atelectasis is a frequent complication of this disease, especially in infants. It is likely that many cases of massive collapse brought about apparently by diverse causes are in reality dependent upon plugging of the bronchial tubes with mucus.

The symptoms of massive atelectasis vary considerably. The onset may be sudden and severe; but the constitutional manifestations are usually mild, consisting of cough and moderate, if any, elevation of temperature, while the respiratory rate may or may not be increased. Physical examination shows dimin-

ished expansion of the affected side, if but one is involved, dullness on percussion, and usually an increase of vocal resonance with loud bronchial respiration. Even in the cases where the respiration is feeble, a bronchial character can be detected. The heart is displaced toward the affected side, but this may not always be discoverable on percussion, owing to possible emphysematous distention of the adjacent edges of the lung. The ultimate diagnosis is believed to rest upon the radiographic appearance, especially when the lesion is on the right side. It is stated to depend upon the triad of collapse of the lung, cardiac displacement to the affected side, and a high stand of the diaphragm on this side. The differential diagnosis from pneumonia, which is the disease most likely to be thought of, rests upon the mildness of the general symptoms as compared with those of the latter disease, the presence of some one of the ordinary exciting causes usually operative, and the x ray data mentioned.

The question arises whether the case now reported fits into the category of massive atelectasis of the lung. Against it stands the early age of the patient and the apparent absence of any discoverable cause for a unilateral active atelectasis. As to the symptoms and physical signs, the extensive consolidation or condensation of the lung, combined with the excellent general condition and the absence of fever, casts doubt upon the original diagnosis of pneumonia, in spite of the fact that the physical signs strongly indicated the presence of this. The x ray examination appeared to be conclusive. As regards the existence of a possible cause in this case it is to be noted that one of the chief symptoms was the unusual interference with the swallowing of food as detailed. This difficulty, as stated, consisted chiefly in regurgitation of milk through the nose when the infant was taking the bottle. The thought arises that there existed here a deficient action of the palate and that very possibly, as a result of the regurgitation, some food may have entered the right bronchus and, through the irritation produced, secretion of viscid mucus and a blocking of the bronchus may have taken place. There is, of course, no proof of the truth of this explanation, but it would appear to be at least a very natural and probable one.

There is a third condition to be considered which, it is true, throws no doubt upon the occurrence of massive atelectasis as a pathological condition, but does indicate a possibility that similar physical signs and especially x ray findings may, particularly in childhood, be dependent upon pneumonia, existing alone or combined with atelectasis; perhaps the one condition or perhaps the other predominating, and either being primary or secondary in development. That pneumonia could produce x ray and other signs of the nature discovered is by no means a new idea so far as adults are concerned, although the occurrence would seem to be a very rare one. Hofbauer (6) refers to displacement of the mediastinum occasioned by unilateral pulmonary infiltration, as a result of the diminished entrance of air into the affected lung; and refers to a similar statement of Curschmann (7). It would appear probable that the condition may occur much more frequently in children and especially in infancy.

Of particular import in this connection is the interesting contribution by Thoenes (8) on Mediastinal Displacement in Infiltrative Disease of the Lungs in Infancy. This writer details eleven cases, in all of which there were clinical evidences of pneumonia infiltration predominatingly, or only, of one lung, and in which an x ray examination showed more or less displacement of the heart to the affected side. The diagnosis of pneumonia was confirmed in four autopsies, in one of which the infiltration was extensive. Atelectasis, too, was found in all, the degree varying with the case. These subjects were all young infants from seventeen days to thirteen months of age, most of them exhibiting varying degrees of malnutrition; but some apparently healthy and thriving when the disease developed. He is of the opinion that both pneumonia and atelectasis were factors in the production of the displacement of the heart and mediastinum; this displacement being aided by the compensatory overdistention of the unaffected lung with air, and more especially by the poor development of elastic fibres characteristic of the lung at an early age. It is evident that a lung largely consolidated by pneumonic infiltration is incapacitated from a satisfactory inflation during respiration, and that displacement of the heart may be a natural result just as it would be in atelectasis.

Thoenes's conclusions are largely supported by the observations of Wallgren (9). This writer has observed a considerable number of cases of pneumonia with displacement of the heart to the affected side. Of these he reports eight in detail with x ray illustrations. He believes that the condition is probably much more frequent in early life, especially in the first year, than these figures indicate. The age of the patients reported varied from two and a half months to nine years. All of them appeared clinically to be perfectly clear cases of acute unilateral pneumonia developing in subjects in good or very fair general health. He believes, further, that a complicating atelectasis in the pneumonic lung adds to the diminished expansion of the affected side and the cardiac displacement which results, but he considers that the pressure of the other lung through its compensatory dilatation is the principal factor.

Here, too, may be mentioned the statement of St. Engel (10) who, in presenting an x ray picture of a rightsided pneumonia, points out that a high stand of the diaphragm on the affected side is of common occurrence in inflammatory conditions of the lower lobe, being dependent upon diminution in the size of the lung through a reflex interference with respiration upon this side.

CONCLUSIONS

Several conclusions seem justifiable:

1. The case here described is probably best assigned to the category of massive atelectasis of the lung, probably in this instance the result of a blocking of a bronchus by liquid food and viscid mucus. The diagnosis might, however, not be entirely justifiable based solely on the x ray appearances, but is so justified when these are combined with the absence of all ordinary symptoms of pneumonia.

2. In view of the extensive difference of opinion regarding the pathogenesis, and because, further, the employment of the terminology "massive collapse" might be taken to denote a separate clinical entity—

as in fact is done—it would seem preferable to call the condition massive atelectasis, as has been repeatedly proposed. In this event the disease is to be considered only a variety of atelectasis differing from other forms merely in degree and to some extent in the method of its production.

3. There is not the slightest doubt that the x ray appearances are of the greatest value in the making of a diagnosis of massive atelectasis of the lung, and that the diagnosis cannot be made with certainty without such examination. Yet, if the observations reported are correct—and it is hardly possible that they are all erroneous—it would seem that pneumonia may at times be capable of producing similar, if not, perhaps, so marked x ray appearances as are seen in massive atelectasis, and that the clinical symptoms must be given serious consideration. To how great a degree a complicating atelectasis may be responsible for this cannot be determined in the present state of our knowledge; especially in view of the fact that pneumonia, particularly when of the catarrhal form and occurring in young children, is liable to be accompanied by atelectatic patches in the diseased lung.

It may be stated in this connection that some investigations are now being conducted in the Children's Hospital, of Philadelphia, which, as far as they have gone as yet, would seem to support the view that the displacement of the heart to the affected side may occasionally be observed in pneumonia, without clinical evidence of atelectasis. Should further studies confirm this, the results will be published later.

The Difficulties of Maternal Nursing

HERMAN B. SHEFFIELD, M.D.

New York

We are all familiar with the enormous advantages of maternal nursing over bottle feeding of infants. Suffice it, therefore, merely to reiterate the fully established observations, that breast milk is a highly nutritious, ideal infant food, destined by nature alike for the poor and the rich, the weak and the strong baby under ten months of age. It has the marvelous and most convenient qualities of requiring neither sterilization, pasteurization, nor even warming, and is ever ready for immediate use at all times of the day and night, at all seasons of the year and in all climes of the world. Yet, like so many other blessed things on earth, breast milk has its limitations in bountifulness, and occasionally presents great difficulties, even when exact laboratory tests prove that its composition is apparently absolutely normal—thus tending to show that in some instances breast milk possesses chemical or biological constituents which in some infants evolve anaphylactic phenomena, rendering the milk unfit for consumption.

In times bygone, when women led a more natural, simple life, and their vitality was not sapped by the extravagances of extreme wealth and the frivolities of society, or the abject misery of extreme poverty of the city slums, practically every woman was endowed with the facility to suckle her babe. But, alas, times have changed and we have changed with them; and do what you will, the greatest majority of the mothers of large cities of today are unable, even if willing, to nurse their babies —the threadbare assertions of the many well meaning health and welfare societies to the contrary, notwithstanding.

I vividly recall the time, when (frequently to the great detriment of the babies' health and, by the way, of my shrunken purse) I also had the fixed idea that I could change the course of modern life; when, following the precepts of my teachers and textbooks, I stubbornly insisted that every mother could and must nurse her offspring. Many a mother have I fattened almost to the bursting point and many others thinned to mere skeletons, hoping by these means to enable them to keep their babies at their breasts, but my efforts only too often proved dismal failures. Finally, after many years of study and close observation, I have come to the conclusion that there are three types of nursing mothers, namely: one group that can nurse her babies, and either does it or does not do it, to suit her own convenience; another group that can not, but is anxious to do so, and a third group of mothers, who could suckle their infants, at least partially, if properly guided by their family physician, before and after the birth of the child.

The first group of mothers comprises mainly the foreign born women of little or moderate financial means. Already as young girls, the fact is firmly impressed upon their minds that maternal nursing goes hand in hand with blessed maternity. It matters little whether or not they have enough to eat or to drink; whether they rest or work, and whether they everlastingly quarrel with their husbands, mothers-in-law or neighbors, or are as placid as

tame kittens—their milk supply is ever plentiful and their babies get prizes on exhibitions. Those of us who are associated with clinics of the slums are often surprised to note how some frail, emaciated little woman has milk enough readily to feed twins, even though her breasts hang down loosely like empty, shriveled up bags—differing very materially from those of the classical Madonna so often stressed upon in our text books as the primary prerequisite in the selection of a wet nurse. In this connection it may be of interest to observe that some of these mothers nurse their offspring not only as a duty to their children, but as a great pleasure to themselves, the manipulation of their breasts during suckling creating in them a sort of sexual gratification. Indeed, I can recall quite a few of the somewhat erotic women who, contrary to my advice, kept on putting their babies to the breasts at short intervals, in order to satisfy their libido; and there is justification for the suspicion that, for the very same reasons, some mothers prolong nursing until their babies are fully capable of partaking a square meal.

In strong contrast to this group of primitive mothers, we meet with another group that embraces the product of our modern civilization, the socalled intelligentsia—with or without genuine sense or knowledge. These women generally measure up to the highest standard of motherhood, as regards duty or sacrifice for their children. Indeed, long before marriage, their thoughts already dwell upon the sacred duties of maternity, and long before pregnancy, they are often engaged in the study of books, scientific or otherwise, on the best methods of rearing ideal infants. Their first thoughts after parturition are concentrated upon their duty to nurse their offspring. They are prepared for sacrifices—to diet, to lose their figure, to give up their pleasures of society and all—in order to aid nature to secrete the vital breast milk, but, unfortunately, the more they sacrifice, the less they succeed. Their intelligence, their hypersensitiveness and their extraordinary anxiety, all combine to thwart their supreme efforts. Encouraged by their conscientious family physician, they try again and again to attain their goal; they coax, indeed, harass, their babies to suck on the fountain of life, disregarding painful, often cracked, nipples and general debility or disease. But, try as you may, the breasts remain as dry as the wild wastes of Sahara—in the everlasting conflict between artificial civilization and crude nature, the latter usually triumphs and cruelly exacts from the former its full penalty with a vengeance.

We are now coming to the third group of mothers, who, though by nature destined to nurse their babies, fail to do so because of the uncanny imposition, especially upon young and inexperienced mothers, of a large number of traditional hard and fast rules and regulations that hinder and impair the normal functions of the breast and nipples. Barely has the mother emerged from the painful ordeal of parturition, when from all sides commands arrive, to fill her up to the brim with excessive quantities of milk, gruels, cream, eggnogs, soups, beer and what not, regardless of her appetite or powers of assimilation of the food. As a result of this forced feeding, we often meet with the following serious consequences: Sudden plethora of milk or undue rise in its percentage of fat, in both events producing indigestion in the infant, and, furthermore, causing caking of the breasts and biliary disturbances in the mother. In fact, there is good reason for the belief that the quite common occurrence of cholecystitis and gallstones in mothers soon after parturition is often the direct result of the aforementioned method of overtaxing their digestive organs. Another error that is generally committed, especially in maternity hospitals, is the enforcement of a preposterous standing rule, like clock work, to put the baby to the mother's breast regularly every three or four hours during the day and night, exactly for twenty minutes at a time—irrespective of the comfort or discomfort of the mother and the inherent disposition and vital capacity of the baby. This redtape army regulation only too often leads, on the one hand, to painful and cracked nipples and possibly subsequent breast abscess in the mother, and, on the other hand, to dyspepsia, insomnia and excessive irritability in the baby. Indeed, I have often wondered whether the latter condition does not act as the primary cause of spasmodic pylorus stenosis, since, contrary to what is generally expected, this affection usually predominates in breast fed babies.

Having thus surveyed the vicious forces that militate against natural maternal nursing, I shall now endeavor to offer a few practical suggestions, which may help to minimize, if not wholly to eliminate, the difficulties. First of all let me emphasize the fact that, with our present knowledge of sanitation, the strict supervision of the milk supply by the departments of health, as well as by the medical societies and, finally, the facility with which every mother can modify the baby's food at home in accord with her doctor's directions, millions of babies are nowadays as successfully reared on cows' milk as on human milk. The view frequently expressed by breast milk fanatics that breast babies are less susceptible to contagious diseases than bottle babies is, to say the least, a gross exaggeration of but a scintilla of truth. We all know that practically the majority of infants under six months of age are more or less immune towards infectious diseases; and, taking, for instance, one disease (pertussis) as an index, I had occasion to observe and to report (1) more cases of whooping cough in the newly born and young breast fed infants than in the bottle fed. Now, the statements here made are not intended to convey the impression that maternal nursing is to be abandoned, nay condemned—quite the contrary! Maternal nursing is the ideal, the most convenient feeding for babies, and, under favorable conditions, should by all means be fostered and urged upon mothers as a bounden duty towards their offspring. But, when it is a question of making cows out of women, when it is a question of giving them all sorts of trouble, of disturbing the peace, comfort and serenity of a home and the family by a spasmodic colic baby that keeps wife and husband, kin and neighbor in a state of uproar day and night, then, by all means, give the baby cow's milk, bottle and nipple and all. We must ever bear in mind the fact that every mother is a separate unit with special inherent as well as acquired characteristics

that cannot be remodeled at will to suit special occasions. And, if any molding to become a model wet nurse is to be done at all, it must be started long before the baby is born. The prospective mother must be assured that pregnancy, parturition and nursing of the baby are natural, physiological processes, ordinarily devoid of perilous complications or sequelæ. During the later stages of pregnancy, she must be put in the most healthful physical and mental condition, free from the anxieties of the struggle for a livelihood, as well as from the nerve wrecking and tantalizing allurements of a luxurious and frivolous life. Towards the end of pregnancy the nipples should be hardened by means of hot boric acid solutions and glycerite of tannin. If necessary, the nipples should be stimulated in their development by gentle massage and traction with the fingers or breast pump.

Except where surgical interference is anticipated (such as abnormal positions of the baby, narrowness or other deformities of the pelvis, placenta previa and the like), the patient should preferably be delivered at home, rather than in a hospital, provided, of course, the patient lives in a modern clean apartment or house and can afford the services of a good nurse who is capable successfully to meet emergencies. The objections to the hospital are mainly the facts that the great majority of good women are loath to separate from their homes and husbands and possibly other children, and that the very idea of going to a hospital has a depressing effect upon them. Furthermore, when there, they are often disturbed by the sufferings of other patients, by the odors of anesthetics and antiseptics, etc., and, last but not least, in the hospital they, as well as their babies, are more exposed to infections, which directly or indirectly interfere with proper maternal nursing. Heaven forgive me for whispering that I have seen many a mother with infected breasts and many a baby with general furunculosis or impetigo who contracted the infections in some of the best regulated maternal hospitals of our great city.

After the mother has fully recovered from the shock of accouchement, and both she and her baby are in a normal condition, it is advantageous to put the infant in her room, instead of in the remote, generally overheated and poorly ventilated nursery, in order to afford the mother the exhilarating joy of watching the wonderful creation of nature through the medium of her personality. This preoccupation generally diverts her mind from the numerous physical or mental disturbances that are associated with postpartum.

As already suggested, overfeeding of the mother is sternly to be avoided. During the first three days after delivery, she may receive in twenty-four hours one quart of milk with cereals or toasted bread in addition to vegetable broths, stewed fruits and a small portion of chicken or lamb for dinner and one egg for supper. The diet thereafter should gradually be varied, so that by the time she is out of bed she may enjoy the meals she was generally accustomed to. The obsolete tradition that mothers' milk is improved by "slush" and deteriorated by a good substantial diet is as preposterous as the other—often for nurses and physicians very convenient—ancient heirloom, that breast abscess is the result of a socalled cold.

After gentle sponging of the baby's mouth and its mother's nipples by means of absorbent cotton dipped in warm boric acid solutions, the infant should be put to the breast about twelve hours after delivery, in the meantime administering every four hours a few ounces of water with or without a pinch of cane sugar. It should nurse on one breast only, from five to ten minutes at a time, every three or four hours, when awake. When sound asleep and prefectly comfortable, it should not be awakened at specified intervals, to suit the conveniences of the nursery authorities. If the mother's milk supply is scanty and the baby is hungry, it may receive as an additional food immediately after nursing one or two drams of milk in one ounce of water, preferably through a bottle and nipple, in order to accustom the baby to proper sucking. Whenever the mother's nipples are hypersensitive or underdeveloped, or show a tendency to crack or bleed, an ordinary glass nipple shield will be found a grateful temporary substitute for the mother's nipples.

About one week postpartum an inventory, as it were, should be taken of the mother's milk supply. This is best determined by weighing the baby before and fifteen minutes after nursing, the gain in weight indicating the approximate milk content of the breast. Also, with a fair degree of experience, one can readily gauge the quantity of the milk by "stripping" the breasts, i.e., gently grasping the breast at the pigmented areola with thumb and index finger and, with gentle pressure, repeatedly move the fingers toward the end of the nipples. With normally secreting breasts, these manipulations produce several jets of milk which spurt freely and distantly in all directions. Sometimes this is only accomplished after the baby had already been sucking for a minute or two, i. e., after the flow of milk had fully started. The quality of the milk can usually be determined by laboratory tests and by the appearance of the stools. Excess of fat, which is the most disturbing element in breast milk feeding, is readily detected by an oily appearance of the stools, with small white lumps resembling bits of cream cheese. If the breast milk agrees with the baby, we generally find that the baby suckles peacefully for about ten minutes and falls asleep at the breast. Otherwise, it usually squirms and belches uncomfortably, off and on drops and grasps the nipples and, as it were, digs into the breasts, and is not fully content, even after lying at the breast half an hour or longer. As a rule, the mother interprets this action of a baby as a sure sign of not getting enough milk, hence keeps it at the breasts, sometimes even for an hour at a stretch, of course, without benefit to the baby, but to the detriment of her nipples and her general health. As a matter of fact, however, this behavior of the baby may be due either to an excess of milk as a whole or to its fat content only. In either event the trouble is readily remedied by recommending to supplement a whole milk formula, in addition to ten minutes nursing, in case of insufficiency of milk; and a skimmed milk formula, after five minutes nursing, where the milk is too rich. The formula is prepared

as usually, in accord with the age of the infants, the amount varying with their natural propensity and appetite—some of them drinking only part of the mixture, and others again voraciously emptying the whole amount prepared for them. In this manner we are usually able to continue maternal nursing to the great benefit of both mother and child, often until weaning time. Failing, however, to obtain satisfactory results with the aforementioned procedures, we generally withhold the breast milk entirely for from twenty-four to forty-eight hours, resort to bottle feeding, and watch the effect. If the cows' milk mixture fully agrees with the baby, while resumption of breast feeding recreates the same discomfort, restlessness, colic or vomiting, I do not at all hesitate to discontinue breast feeding entirely. After doing so I almost invariably find that the babies thrive beautifully on well chosen cows' milk formulas; furthermore, that the mothers' breasts require no remedial measures to arrest their secretion of milk—thus proving conclusively that the breasts were kept barely alive artificially by forced feeding, and would not have lasted long at best.

Congenital Malformations of the Rectum and Anus*

J. F. SAPHIR, M.D.

New York

According to statistics, Bodenhamer in 1860, in an extensive and exhaustive report, showed that anorectal malformations are present in one in every ten thousand infants. Those with abnormal openings into the bowel live and in time are brought to the hospital or the physician because the condition is a puzzling one. Complete imperforation of the anus or rectum causes death in a few days unless relieved.

The rarity of the condition prompts me to present the following cases that I have seen recently:

Case I.—Baby B. H., male, fourteen months old, was referred to me by Dr. S. C. G., June 16, 1922. The history given to me was that the child was born without an anus. This was probed when the child was twenty-four hours old, since which time the child dribbled some fluid fecal matter from the probed opening, and some fecal discharge was also seen to pass through another opening situated anteriorly and near the scrotum.

The child never had an abscess, or a discharge of pus from the anus or perineal parts. The anus and perineum became raw and excoriated, the child had three to four fluid evacuations a day, some days—and at other times must have cathartics or he became greatly distended.

Examination revealed an apparently healthy child, well formed and well nourished—rectal inspection showed the presence of a fold of skin obstructing the opening of the anus, and extending anteriorly to the scrotum; underneath this fold of skin near the scrotum there appeared tracts simulating fistulous canals on probing, but which were filled with fecal particles.

The following day, June 17, 1922, under the influence of one half per cent. of novocaine as a local anesthetic, I excised the folds of skin, by incision and trimming of the skin edges, eliminated what appeared to be the fistulous tracts; and on getting to the anus found a congenital narrowing of the anus and rectum. I split the anus and rectum posteriorly, trimmed the edges the same as I would do in a fissure operation, and sent the child home the same evening. For the first time since birth the child had satisfactory and formed movements. The child was brought to me for treatment and dilatation of the anus and rectum for about eight weeks.

However, I advised the parents that it might become necessary to enlarge the opening or do some plastic work on the anus when the child became older. On May 13, 1923, eleven months later, again with one half per cent. novocaine as a local anesthetic, I operated on the child. A contraction had formed which made it difficult for the child to move its bowels, and by splitting the sphincter muscle, and with slight plastic work, the child now has a useful anus and rectum, moves its bowels regularly every day, and has made an uneventful recovery.

Case II.—Baby H. J., female, five weeks old, was referred to me by Dr. I. F., June 12, 1924. The parents said that the child cried at every attempt at evacuation, and that to them it seemed that there was something abnormal about the anus; there was no blood with stool, and the child seemed healthy but cried at every attempt at a bowel movement.

Examination revealed a distinct occlusion of the anus by a transverse fold of skin, which also projected backward to about the location just over the tip of the coccyx.

Under local anesthesia of one half per cent. novocaine I excised the fold of skin, split the anus posteriorly, and found the narrowing of the anus for a distance of about one and a half inches and allowed the posterior slit to heal by granulation. The child was sent home from the hospital the same evening, and was brought to me for treatment about twice a week for six weeks for dilatation, and had been having very well formed movements for about four months, when again some difficulty or contraction was noticed.

November 22, 1924, five and a half months later, due to this contraction having formed, it became necessary to do a slight plastic operation, after having removed the scarred and thickened tissue as in the preceding case. Up to date the child is well, and is brought to me for examination once a month.

*Presented before the American Proctologic Society, Atlantic City, May 25, 1925.

Case III.—Baby R. W., female, four and a half months old, was referred to me by Dr. W. F. P., November 18, 1924. This was the mother's first and only child which felt well until six days ago when the child began to cry, the stomach became distended, and the child was straining at stool as if she wanted to move her bowels—but the child never passed more than discolored fluid. The young mother in desperation, not knowing what to do, asked her mother what should be done, and she was advised to give the child an enema. She prepared the solution, and when she tried to give the enema, couldn't find a place to insert the enema tip, and as the mother expresses it, "when she looked at the rectum it didn't look right." Previous to this experience the child had had fluid movements three times a day, which the mother thought was normal—she knew no different.

The mother became frightened, took the child to her family physician who referred her to a pediatrist, and then the pediatrist referred her to me. After a three and a half hour trip from New Jersey, she arrived at my office, the child continuously crying, the belly distended, the legs flexed, and bent upon the abdomen, beads of perspiration on the child's head and severely straining.

Examination revealed a pin point opening where the anus should have been, and I could with difficulty insert an extremely fine probe.

I felt there was no time to lose to send the child to the hospital, and in my office under the influence of one half per cent. novocaine as a local anesthetic, I injected the parts, and dissected down posterially toward the coccyx, then upward and found an extremely contracted tubular anus and rectum for a distance of about one and a half inches, which consisted of dense, tough fibrous tissue which I removed. I split the sphincter muscle. The child expelled an enormous amount of hard fecal matter, and manually I was able to break up and remove the rest of the rectal contents—the child relaxed; distention and straining were relieved—I did a perineal excision of the entire fibrous mass, drew down the healthy rectum and sutured it to the skin, applied a sterile dressing and sent the child home. After eight weeks of treatment the child made an uneventful recovery, and has a perfectly useful anus and rectum.

These cases are interesting, not only on account of their rarity, but also because of the prompt relief that can be given in them without any untoward results under the influence of local anesthesia.

A fourth case was omitted for lack of space. It will be included in the reprints.

Corn Meal in Infant Food Modifications

GEORGE DOW SCOTT, M.D.
New York

The first solid food added to the milk modifications in the infants' dietary is the cereal given from about the fourth month on, depending upon the individual infant. The selection and proper preparation of this cereal is in consequence a matter of great consideration. For in the selection of this cereal for the individual infant the burdens, perplexities and worries of the first year may be appreciably lightened. At present grains are generally used for their high carbohydrate valuation. Carbohydrates yield the most important oxidizing material with the least expenditure of effort on the part of the growing child. They are biologically economical on account of their complete utilization and because the energy required for digestion is much lower than for the fats and proteins. Carbohydrates are nitrogen retentive and aid in the digestion and assimilation of these fats and proteins. They have a water retentive value especially noticeable in those cases of marked malnutrition in which there is a dehydration as well as a loss of salts. This is made manifest by the smaller amount of urine excreted during cereal gruel feedings than when no cereal is used, although the fluid intake is the same (1).

Cereals in general may be grouped into three classes, 1, the oat group; 2, the wheat group; 3, the maize group. The oat group, says Chamberlain, stands at one end as typical muscle or energy producing food, while the maize group brings up the other end as fat and heat producing (2). In cereal grains, while starch is practically the only carbohydrate present, some sugar is contained in them in small quantity, except in sweet corn and in sorghums where it is found in large amount (2). Besides carbohydrates, fats, mineral matter, phosphorus for example, although the grains are deficient in calcium, and a certain proportion of water, there are also present grain proteins. These proteins vary much in kind in the different cereals and their value as tissue formers varies also. Small quantities of other nitrogenous substances exist called anides. The proportion of fat varies in different members of the cereal group and is most abundant in the cereals of northern latitudes but are almost absent in the cereals of the tropics (3). The general composition of cereals is practically as follows:

	Percentage
Water	10-12
Proteins	10-12
Carbohydrates	65-75
Fat	½- 8
Mineral matter	½- 8 (3)

Furthermore, cereal grains in relation to their nutritional contents may be roughly divided into two general groups, the one typified by oats or wheat, high in protein and relatively low in carbohydrates, the other typified by maize relatively low in protein but rich in carbohydrates and is moreover of great nutritive value (2). Oats and corn are two distinctly different cereals and the differences in the amount of nutritive constituents are considerable. On the other hand, the cereals rye and wheat are very similar and show but slight differences in the amounts

of their nutritive constituents (2). While corn, wheat, rice and oats form a large group of foods that contain a large amount of starch and an amount of protein at least above the average for food materials in common use, of them all corn preparations are among the most economical of our common foods (4). Chemical analysis shows that maize is quite as nutritious as wheat except in mineral constituents, richer in fat than any cereal except oats, containing twice as much as wheat or barley and three times as much as rye. In nitrogenous matter corn products are slightly inferior to most of the other cereals and its carbohydrates are equal to wheat but somewhat inferior to those of rye and barley in digestibility (3). While it is true, says Chamberlain, that the amount of productive energy in one hundred pounds of maize is greater than in an equal amount of oats (some 23,000 calories) or that because one hundred pounds of maize will produce an increase in flesh five and a half pounds greater than can be produced with an equal weight of oats, is maize to be considered more valuable than oats? Or again, because the nutritive value of oats is four to seven per cent. lower than that of maize are oats consequently of less value? (2) However, be that all as it may, the following list of the average composition of corn and corn products shows the great value of this cereal as food (5).

AVERAGE COMPOSITION OF CORN AND CORN MEAL PRODUCTS

	Water, p. c.	*Protein p. c.*	*Fat, p. c.*	*Starch, p. c.*	*Crude fibre, p. c.*	*Mineral matters p. c.*	*Fuel value per pound—calories*
Corn—whole grain—average	10-8	10-0	4-3	71-7	1-7	1-5	1-795
Corn—white	11-4	10-8	5-0	68-8	2-5	1-5	1-690
Corn—yellow	11-9	10-7	4-8	68-9	2-2	1-5	1-690
Cornmeal (whole grain, ground, unbolted)	12-0	8-7	4-7	71-11	2-2	1-3	1-850
Cornmeal (whole grain, ground, bolted)	12-0	8-9	4-9	72-0	1-2	1-0	1-765
Cornmeal (granulated, new process)	12-5	9-2	1-9	74-4	1-0	1-0	1-770
Corn flour (meaning finely ground and bolted cornmeal)	12-6	7-1	1-3	77-5	-9	-6	1-645

All biological research workers speak of the high nutritive value of corn products; many speak of their superiority over other cereals in this respect; while many more speak of their energy value as higher than found in other cereals. Maize contains several proteins and under certain conditions corn products are of more intrinsic value than meat for their proteins are well and thoroughly utilized. Malfatti according to Mendel and Fine found that the digestibility of maize was eighty-two per cent. (6). The following biological research work by Mendel (7) and by McCollom (8) will, I believe, show the great value of corn and its products at least in animal experimentation.

Mendel writes in part of this interesting animal experimentation: Theoretically he says it has seemed easily possible (for some physicians) to construct a balanced ration largely on the basis of analytical data expressed in grams of digestible proteins, carbohydrates, fats and inorganic salts, and in total calories of metabolizable foodstuffs. An elaborate investigation begun about fifteen years ago at the Wisconsin Agricultural Experiment Station showed in a most striking way that there are physiological values to a ration not measurable by the current chemical methods or dependent upon mere supply of available energy. Comparisons were made of the effect rations balanced from corn, oat and wheat plants respectively had upon growth and reproduction in cattle. Rations restricted to the corn plant were highly successful for both growth and reproduction, while rations restricted to the wheat plant were disastrous to successful growth and reproduction. The tests with a ration made from the oat plant indicated at that time (1911) that it was not possible to make a highly successful ration from rolled oats and oat straw.

McCollom, speaking along the same lines, has summarized some interesting tests. The object was to determine whether rations for cattle so made up as to be alike in so far as could be determined by chemical analysis, but derived each from a single plant, would prove to be of equal nutritive value for growth and the maintenance of vigor. The ration employed for one group of animals was derived solely from the wheat plant and consisted of wheat straw, wheat gluten and the entire wheat grain. The ration of a second group consisted of the entire corn plant which included the kernel, stalk and the leaf together with a portion of corn gluten, a byproduct of the corn starch industry.

The third group obtained their ration solely from the oat plant, being fed entirely on rolled oats and oat straw and leaf. There was a fourth group which it was supposed would serve as controls, that was fed a ration having the same chemical composition but derived from about equal portions of wheat, corn and oat products. The animals employed were young heifer calves weighing about 350 pounds, and were as nearly comparable in size and vigor as could be secured. They were restricted absolutely to the experimental ration. They were given all the salt (sodium chloride) they cared to eat, were well cared for and were allowed to exercise in an open lot free from vegetation. Their behavior during growth and during the performance of the function of reproduction was extremely interesting. All groups ate practically the same amounts of feed, and digestion tests showed that there were no differences in the digestibility of the three rations. It was not until the animals had been confined to the experimental rations for a year or more that differentiation in their appearance was easily observable. The corn fed group was sleek and fine and evidently in an excellent state of nutrition. In marked contrast stood the wheat fed group. These animals were rough coated and gaunt in appearance and small of girth as compared with those fed the cornplant ration. The weights of the two groups did not differ in a significant degree. The groups fed the oatplant ration and the mixture of the three plants, leaf and seed stood intermediate between the lots just described. The assumption that the animals receiving the mixture of products would fare better than the others and thus serve as the standard group of controls did not prove correct. The cornfed animals were at all times in a better state of nutrition than were those receiving the greater variety of food materials.

The reproduction records of these animals are also of special interest. The cornfed heifers invariably carried their young to full term. The young showed remarkable vigor and were normal in size and able

to stand and suck within an hour after birth, as is the rule with vigorous calves. All lived and developed in a normal manner. The young of the wheatfed mothers were the reverse in all respects. They were born three to four weeks too soon and were small, weighing on an average forty-six pounds, whereas the young of the cornfed animals weighed seventy-three to seventy-five pounds each. The latter weight is normal for newborn calves. The young of the wheatfed mothers were either dead when born or died within a few hours. The young of the mothers which had grown up on the oatplant ration were almost as large as those from the cornfed mothers, the average weight being seventy-one pounds. All of the cows in this group produced their young about two weeks too soon, one of the four was born dead, two were very weak and died within a day or two after birth, the fourth was weak but with care it was kept alive. The young of the cows which were fed the mixture of the three plant products were weak in most cases. One was born dead and one lived but six days. The mothers were continued on the experimental rations and the following year they repeated in all essential details the reproduction records observed in the first gestation periods. The observation was made that the urine of the wheatfed animals was invariably distinctly acid in reaction whereas that of the other lots was alkaline or neutral. It was not possible by any means known to biological chemistry to work out a reason as to the cause of the pronounced differences in the physiological wellbeing of the different lots of cows.

The importance of the proper grinding of the coarse corn is a great one. The fineness of grinding and the removal of the coarse parts of the skin or bran makes some difference in the digestibility. The amount of the germ and of the skin removed when corn is milled affects its food value as well as its appearance, flavor and keeping quality. When the germ is removed most of the fat and all of the vitamine A go with it, whereas when the skin is removed the meal contains less cellulose and a little less protein, less mineral substances and less vitamine B. The stone grinding of maize, or the old process of grinding by primitive races, was a great improvement over the socalled new process (5). The old process stone grinding retains most of the germ and usually more or less of the skin. Therefore nearly all of the protein is included as well as the fats, the mineral matters, the cellulose, the vitamines and the starch of the corn. Such meal feels soft and flower-like to the touch. In the new process where the corn is ground with the aid of steel rollers or disks, most of the germ and skin have been removed, the resulting meal contains less protein and much less fat, mineral matters, cellulose and vitamines than results from the old process, for as can be readily seen, the old process left in the meal much that the new process removed. In the removal of the skin of the corn six one hundredths of the whole weight of the grain and more than half the fibre has been extracted. In the modern milling of corn the germ is removed which takes away incidentally only one tenth of the weight but more than six tenths of the fat and one sixth of the proteins, and removes all the vitamines (5).

The final step in the preparation of the cornmeal for the infants' food is in the cooking of it. The flavor and appearance are improved and a better digestibility is gained thereby. Long cooking converts the nutrients found in the corn and other cereals into more digestible forms and this extended cooking is extremely important in foods which contain so much starch. Since this starch is surrounded by crude fibre largely cellulose in character upon which the digestive juices are unable to act, this wall must be broken down for the most part through cooking. The softening of this cellulose is best accomplished by cooking a long time with much moisture as seen in steaming or in boiling. Whole or partially crushed grains as resulting from the old process of grain milling require longer and more thorough cooking than the meal of the new milling process. When a cereal is improperly cooked there is always danger of the loss of the valuable nutrients through failure of digestion and through the severe irritability of the intestinal mucous membrane. In boiling cereals some of the surrounding water is absorbed and many of the nutrients pass into the remaining water. In consequence, if the water is thrown away, these food principles are lost. Steaming is, therefore, I believe, the only effectual way to prepare cereals, particularly cornmeal, for the infants' diet (9). This steaming causes the starch grains to swell and rupture their cellulose envelopes, the starch on cooling is said to be gelatinized and in this form may be kept on ice. This change takes place in cornmeal below the boiling point, in fact at a temperature of 167° F. (3).

The digestibility of the cornmeal preparation is, to repeat, almost wholly dependent upon the long cooking process. In steaming, the double boiler is preferably used. Its ingredients are water, salt and cornmeal. From one half to one teaspoonful of salt for every cup of water used. The proportion of cereal to water varies according to the kind of cereal used, the method of manufacture and the consistency desired, as seen in the thinner gruels, the thicker mush and the still thicker porridge. Four times as much water by weight as cereal is a good working basis. Add the salt to the water and boil the mixture in the inside part of a double boiler. To the boiling water add the dry cereal slowly, but stir the whole quickly. Boil for three to five minutes, put on the cover, place the kettle on the outside part of the double boiler which should be filled one third full of boiling water, keep the cover on for six hours. Cornmeal should be mixed with an equal volume of cold water before being stirred into the boiling water of the double boiler to avoid lumping (10).

While some authors have found that certain infants have the power of converting starch into sugar soon after birth, yet the majority are freer to admit that this power is seen only in a fairly considerable number. All readily agree that after the sixth week its evidence is indisputable. After six months, however, this saccharifying power is considerable in foods which contain starch. The sugar assimilation power of the infants' liver is about three times that of an adult (Grosz). At birth the amount of trypsin, amylopsin and steapsin is much less than in adults (11).

The food requirements of an infant vary markedly as to season, climate, environment and growth impulse, and each infant requires an individual amount not to be reckoned with that of other infants. In the addition of a cereal to the infant's diet, it is impor-

tant to consider the cereal, its digestibility, the amount and kind of its nutrients, and not primarily the number of calories it contains. For, says Cathcart (12), the caloric factor may be regarded as strictly secondary to the supply of material. We do not live on calories, yet all our general estimates of food requirements are quite properly for the most part in terms of calories. Caloric value is simply a very convenient physical standard for the assessment of diets, but merely because such a standard has proved of great utilitarian value, there is no real justification for placing this standard as the foundation stone of hypotheses framed to offer an explanation of cellular activity. The infant's organism is not a heat engine.

I have been using the yellow corn meal, prepared by the new milling process, for about three years with good success. There is no preference of the yellow over the white meal, as each type possesses about an equal number and equal kinds of nutrients. Beginning its use about the fourth to fifth month, I begin by adding one half oz. once a day, later one half oz. twice a day, etc. Then I add one oz. once a day, later twice a day, etc., gradually adding an amount which the infant, combined with an additional balanced ration, can assimilate. Whether it is from the high starch tolerance of the infant or from the starch and sugar content of the corn meal, or whether the grain possesses qualities which the biological chemist and investigator have not discovered, I know not. However, I do know that the infant grows well, its growth impulse is stimulated, its musculature is strengthened, and its flesh becomes pink and rosy. The research work of Mendel and McCollom would seem to show that corn and its products possess superior qualities of energy or something which other grains lack. Farina, usually recognized in this country as a wheat product, with also the oat, barley, wheat, and rye grains have not given me markedly brilliant results in infant feeding. In spite of a well balanced ration in well fed infants with no gastrointestinal fermentation or intoxications observable, the patient has had a pale skin and pale mucous membrane, soft musculature, and there is a tendency to delayed and painful dentition, and from weeping mucous membranes a tendency to adenoids. In less healthy children there is seen gastrointestinal fermentations or intoxications and a lack of energy and vitality. Up to four months of age I use skimmed milk and cream mixtures, and from the fourth or fifth month on whole, raw, unpasteurized milk, gradually adding the corn meal preparation. In my experience, the infants' tolerance for fat before the fourth month is uncertain and individual, and cannot be computed mathematically.

The gain in weight of infants from the use of cereals cannot ever be said to arise from the food alone. A balanced diet means that all the food stuffs are in proper proportion for that infant and that the addition of any one food principle means the cooperation of all the others in adequate metabolism. The infant has the power, as a matter of fact, of transferring forty per cent. of the protein of its food into new structural machinery, and the nitrogen equilibrium can be better maintained on a higher food intake of fats, carbohydrates, and inorganic salts than from an excess in animal proteins.

The gelatinous corn meal can be kept on ice almost indefinitely, and whenever it is to be used is well strained through a thin meshed colander when it easily passes through the nipple of the bottle.

At times when the infant has seemingly arrived at a starch tolerance stage, which happens sometimes during the warm, muggy days of our summer, I find it best to substitute either the oat or wheat meals, which possess a high grain protein with a relatively low carbohydrate content. During this murky period it is well to examine the urine and to test the feces for an excess of fat and for acid fermentations.

In conclusion, I may say that in the three years of my clinical experiments with yellow corn meal, I have used both the oat and wheat meals as controls. The results would lead me to believe in the higher potency and in the higher energy value of corn meal over the others. As a large proportion of all the gastrointestinal disturbances seen in infants are directly due to an unbalanced food intake and to a resulting unbalanced metabolism, as well as indirectly to a faulty psychological and physical environment, it is of great importance that the pediatrist proportion all the food elements in the infant's diet, as well as he is able for that individual infant under observation.

The author's references will appear in his reprints.

Therapeutic Pneumothorax in Pulmonary Tuberculous Children

P. F. ARMAND-DELILLE, M.D.
Paris, France

Every pediatrist knows how grave pulmonary tuberculosis is in children, so any treatment that might aid this condition toward bringing about a cure should be tried.

From 1922 to the end of 1924 I was in charge of a ward of tuberculous children in the clearing station (Benjamin Franklin Pavilions) of the Debrousse Hospital in which we received all the cases of pulmonary tuberculosis from the children's hospitals in Paris. There I had the opportunity of trying various treatments. There were more than one thousand cases sent for observation and I discovered that in about nine per cent. the indication for practising artificial pneumothorax was favorable, that is, unilateral tuberculous lesion in one lung.

This means that the lung tissue only is unilateral, because in children the brachiobronchial adenopathy is always bilateral, and therefore a pneumothorax is of no value.

The greatest number of our cases have been in children between four and fifteen, especially girls between eleven and fifteen years of age, because, as is wll known, pulmonary tuberculosis is more than twice as frequent among girls as boys of this age. I

have also had the opportunity to practise artificial pneumothorax on two younger children, one eighteen months and the other of seventeen months old, and the operation was completely successful. Both infants were operated upon more than ten months ago and the reinsufflations are still done. Both have gained about seven pounds since that time, have no fever, no cough, eat well and their general condition has improved.

In the beginning of my experiences I practised artificial pneumothorax only in those far advanced cases with cavities, and in a few others with rapid caseifications, or with bad hemoptysis. After my first year of success I decided to practise pneumothorax when the x ray showed only one lung affected and when tubercle bacilli were found in the sputum which was examined in the gastric fluid extracted by catheter if the child did not expectorate; also in a few cases of tuberculous splenopneumonia and when one could not get any expectoration and consequently could not find tubercle bacilli.

I recently read an article by Eliasberg in which this author stated that he had obtained the same result in nineteen per cent. of the cases in pulmonary tuberculosis in children on which he practised pneumothorax. In one out of five cases adhesions of the pleura were found. In our first series we found indications for pneumothorax in only seven per cent., but as we have started doing pneumothorax in incipient tuberculosis in one lung, our percentage could equal that given by Eliasberg.

It is not possible in this short article to emphasize the technic sufficiently. It has been developed in special works published in medical journals in France. I can only say that we use the same method for adults with the Kuss apparatus, mostly applied in France, and that we do the puncture, if possible, in the third or fourth intercostal space on the anterior axillary line, but sometimes in a lower part of the chest, if we find local adhesion in this place.

For the first injection we prepare the child with hypodermic injections of scopolamine morphine suitable to his age, and also produce a local anesthesia with novocaine, but the succeeding puncture is done without any anesthesia. For babies, the general anesthesia with chloroform is necessary because in crying the pressure is increased in the chest. In the first puncture we first inject fifty c. c. of oxygen, then two hundred to three hundred c. c. of nitrogen; in the other punctures, from two hundred to five hundred c. c., depending on the resorption of the case, but with children one must reinject every other week instead of every three weeks. The pressure in the injection must never come over the O of the manometer because if one obtains a positive pressure a deviation of the heart and mediastinum may be produced. Under normal conditions the first injection shows in the pleural cavity a negative pressure of about 14 in inspiration and 4 in expiration, but if there are more or less adhesions, you immediately get a positive pressure before having injected three hundred c. c. of nitrogen.

In my one hundred cases I have never had a serious accident. In young children I observed sometimes a little subcutaneous emphysema if the child cried between or after the injections, but it has always disappeared rapidly. In twenty-five per cent. of the cases I could observe the production of more or less fluid after various intervals of time, but in most cases this fluid is spontaneously reabsorbed without aspiration. It was always serofibrinous and transparent, only in two patients, who died, it was purulent. In some cases precocious readhesion of the pleura was produced and new insufflation of nitrogen was rendered impossible.

The results of this operation are the most important question. As immediate results I observed in all cases a great improvement; the temperature became normal after the first injection and continued normal. In seventy per cent. of the cases, particularly with the girls, after the injection a regular increase of weight was noticed, some of them gaining about fifteen kilos in two or three years.

In all my cases up to the present I had only three deaths: two patients died from purulent pleurisy, and one from tuberculous meningitis, but I think that if these children had been left alone without pneumothorax about seventy per cent. of them would have died. Now five of them can be considered as fully cured. Not only are all clinical symptoms absent, but radioscopy and radiography show *restitutio ad integrum* of the infected lung and it is impossible to know which lung has been tuberculous.

I consider it advisable to continue the injection if possible for three years. I agree with Buruant from Leysin, who considers that for adults this time is necessary for the cure of the pulmonary lesions. In a few cases, indeed, in which for different causes, or because the children were taken to the country and were not sent again to the hospitals by their parents, one observed one progressive adhesion of the pleura that was impossible to stop, namely, the lesions which seemed to be healed presented a new development when the lung was no longer collapsed, and tubercle bacilli appeared again in the sputum.

Twice I had the opportunity of doing a bilateral pneumothorax, as it is done for adults. One of the patients died from progressive tuberculosis, the other after six months is doing well and getting along satisfactorily.

For a certain number of my patients who were operated upon the first time in 1925, it is too early to say that they will continue to be in perfect condition, but I can ascertain now concerning those whom I operated upon in 1923 and 1922. The greatest part of them, that is fifty-five per cent., can be considered as definitely healed: their general condition is excellent, no tubercle bacilli in the sputum.

CONCLUSIONS

1. In every case of unilateral pulmonary tuberculosis in children, with bacilli in sputum, the therapeutic pneumothorax must be done.

2. There is no other curative method, up to the present time, that will cause the disappearance of tubercle bacilli in a few weeks with a real improvement in the general health; no fever, increase of weight, and ability to engage in sports and games with moderate care.

3. In certain cases the therapeutic pneumothorax is the only means of producing a really complete cure, with the disappearance of all symptoms, with normal breathing, no bacilli and normal x ray findings.

Historical Medicine

Hints of Medical and Other Interests in the Odyssey

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

We arrived in the previous number (1) at a point in the Odyssey where we found the subject of drugs and poison and magic. The magic or drugs alone mixed with the drink are very suggestive of the acts of poisoning, real but mostly only reported, which have achieved such wide fame historically as having been practised at the courts of even the earliest Roman emperors as well as at those of the later Roman pontiffs. The historian as well as the scientific investigator has reason to approach such questions with caution. Secrecy in the very nature of the case is desirable and usually easily attainable by the poisoner. But still easier is it for men to malign their fellow men and still more difficult in such cases is it to disprove the libel, and much more prone are men to libel than to poison.

It is natural then also in the Odyssey and in the Iliad, where we find the beginning of what is our literature, we should find the beginning of records of human wickedness far outweighing, from our modern ethical standpoints in other respects than poisoning, those of human virtue. Here in the Odyssey much more than in the Iliad magic and medicine and religion and peace and war are all mixed up together. That was life then and much the same, with variations, that is life today. That is the reason the Odyssey makes a wider appeal to thoughtful men than the Iliad.

FIG. 1.—Apollo and Artemis bringing painless death to the Syrian Isle (Flakemann).

In the Iliad Nestor's concubine mixed a drink for the wounded Patroclus and if we compare the potion Circe mixed for the crew of Odysseus (2a) we note it is practically the same—cheese, barley meal and fresh honey mixed with Pramnian wine. She cast a spell over them which turned them into swine, but it was not with this innocent mixture—I mean innocent of poisonous intent, for digestion it would seem to our prejudices deadly enough. It was with the food apparently she mixed the baleful drug, but it was at a waft of her wand they turned into grunting pigs. One might be forgiven for suspecting Homer meant this as a parable, for one sees something like it, or used to see it in alcoholic days after a cocktail, though after none such as the concubine of Nestor concocted and Circe shook up for the dear friends of Odysseus. The suspicion, however, seems ungrounded for Homer can seldom be detected moralizing and doubtless he loved a lass and a glass of grog and a good song from a minstrel as well as did the people he wrote about. When, however, Circe prepared another enchantment of the kind for Odysseus, who came in later with his eyes opened by the tale told by one of the crew on the lookout for hokussing and further fortified with an antidote given him by Hermes, Circe capitulated and invited him to her bed, after feeding the swine acorns and cornell tree nuts. One often suspects Homer is speaking in parables. Was the antidote Hermes gave Odysseus wisdom from the gods? When Athena speaks to him, it is often nothing but the cautious thought that flashes through his wary brain, it would seem. I am sure that is the proper kind of thought with which to approach such a feast and such a lass as Circe. Later tragedians invented a son, as the result of this meeting of Circe and Odysseus, who killed his father and we may suppose they thought Nemesis had not sufficiently dogged the steps of Odysseus in the Odyssey and something was still coming to him for mounting the bed of Circe who had bewitched his companions with her charms. The whole thing, if it were in the Bible, would ere this have been preached from a thousand pulpits and in ten thousand sermons as the divine wisdom of the East come to us across the ages. Something like their precepts have in every literature been worked into the flowers of literature and rhetoric in every civilized tongue hanging on the details of the tale.

In speaking of the poison Circe gave the crew, it is called bitter. Something bitter was what the arrows were tipped with in both the Iliad and the Odyssey and as we go burrowing back into the Babylonian tiles baked about the time of the sacking of Troy we find poison and bitter were synonymous—the word for both was the same. The antidote Hermes gave Odysseus, disregarding any lurking thought of eastern wisdom hidden in a parable, was a plant dug by him out of the earth. In the last essay we left Homer's early critics complaining that Homer blasphemed in not remembering all the gods as possessed of all wisdom must know medicine too, and here was Hermes betraying a marvelous pharmaceutical skill in choosing simples and Odysseus in telling the tale admits all things are possible to the gods. Now this plant he showed him had a black root and its flower was like to milk. Vaguely groping after it critics, even archeologists, have won-

dered if it were not some faint reflection of the magic plants of the Zend Avesta and the Atharva Veda, the *haoma* and the *soma*. some kind of milkweed perhaps—perhaps it was the juice of the *moly* instead of the flower was white, for poets frequently get things wrong, but the text says flower. Even the unlearned in Sanskrit, Cuneiform and the Hieroglyphs can see an affinity of *haoma* for *soma* and there is a faint suggestion of *moly* for both. Persia is further on the way to India and the Zend Avesta is more akin to the Atharva Veda than to the Odyssey back in the Aegean, but the Aryans, that discredited concept of Nordic people peopling the earth by dripping off from the caravan into choice nooks on their way to the Ganges, may have named the same thing the *moly* as well as the *soma* and the *haoma*. Indeed while we are neighbors to phantasms we might as well admit that *moly* and *soma* and *haoma* and *ginseng* and *siliphon* all belong in the same class, the ever present class of drugs and remedies which pass from the mouth of one exaggerator into the mouth of another poor mortal in every age and in every tongue, for a short year or two or a short civilization or so, but always miraculous. The names may vary and so may the drugs, but the idea is the same. Some god has reached down from heaven and vouchsafed to suffering humanity a miracle to save them from their folly or from the inevitable. That is what Hermes did for Odysseus (2b) and it is no matter whether it is milkweed or ginseng or silphion or onion or garlic or mandrake or opium. Among men of differing civilizations, far separated in space and time, they have all had their adherents, who believed in their virtues as firmly at least as they did in their gods.

Whether we can extract matter of as much medical interest, of as much value to practitioners of medicine as this in the further advice Hermes gave to Odysseus is doubtful perhaps, but it is not entirely devoid of suggestion for the way to handle women, and it is the woman patient who is at once most difficult and most profitable to handle in the way of the doctor earning his daily bread. This advice he got from Hermes is what the connoisseur in the subjection of women not infrequently still uses, but I imagine it has its limitations in the practise of medicine. Abuse her, take a good sized club and beat her, frighten her with fearful threats. The editor and the writer, being married men, stand aghast at such principles held by primitive men and, they earnestly assert, the mere roué. Nevertheless Hermes advised Odysseus, "draw your sword, cut her wand"—they will eat out of your hand and invite you to their beds, these Circes, and so it was. Now was this what Odysseus, that much traveled man, versed in the ways of many cities and many lands, well acquainted doubtless with women and their wiles, was turning over in his mind as he walked over to Circe's house when he had heard from Eurylochus the story of those who had gone on before or did he really meet Hermes on the road with the *moly?*

The cloisters of reformed ecclesiasticism are poor places to read the Odyssey in. From Xenophanes and Plato to our day it is not in the light of the principles of Wesley and George Fox one must view the genius either of Shakespeare or Homer. They take the gods as they find them, manufactured it may be by dissolute and reckless men. Homer found Zeus steeped in amours and he sang the loves of Ares and Aphrodite. He found Hermes and Athena up to the worst sort of deceit and so he reported them. It is not his fault primitive men made their gods thus. We in our day would not have thought the information divinely ethical which Athena gave Telemachus or one calculated to make a son cherish the memory of his father when she related how once he went to Ilus Memerides seeking a man killing poison, not poison gas, which the fathers of this approaching generation got out of the laboratories of science, but poisonous plant juices, probably, to smear on his bronze tipped arrows. John Wesley and Xenophanes would not approve, but that is what the future poet of the great war is going to tell the sons of the heroes who fought in it. Homer didn't make any ethics.

One is curious to know what sort of poison Odysseus begged of Ilus (2c) who was too good to give it to him for it seems there were objectors and would be reformers, even in Homer's day, crying in a wilderness. Some one else gave it to him and Homer goes so far as to intimate Pallas Athena did not think it was nice. It is supposed considerable fuss was made about this incident in Athens when it became finical in the time of Pisistratus and the Athenians interpolated the mild disapproval of Athena, their sheltering goddess, but for my part I do not believe a word of it. Homer shows there are always a wicked majority plotting and carrying out evil among men, and the gods and a select ethical minority among men objecting in a futile manner. So it has been in our day, so it was in Homer's and—but prophecy is no more in my line than Homer's.

We wonder what kind of poison gas—arrow poison—as historians of science we wonder what kind of arrow poison was in use in Homeric days. Curare and the juice of the strychnos plant have been identified as the poison smeared on the points of their arrows by savages, chiefly for the chase as it would seem a certain degree of advance in civilization is necessary for their introduction in war. Some less understood derivatives from the genus Euphorbia have been used in various parts of the world, but what Odysseus sought from Ilus for use in war we do not know. It has been said arrow or spear points dipped in putrid infectious material have been noted in the remote jungles of Africa, but if they were reported as used in the chase we may conjecture some ethnologist was drawing on his imagination, unsupported by his intelligence. For war purposes it is more plausible, but for use in the warfare of advanced nations this and other bacterial poisons are yet in the future for improvement in the munitions of war.

In the Odyssey then we find man running true to the breed and vastly more busy shortening the life of his fellow man by violence and by poison in the cup and on the arrow tip than to prolong his own, except he is always hoping to outfight or outwit his enemy. Nevertheless we are not infrequently reminded that he had thoughts of sanitation, confusedly mixed with his magic and his religion. Homer even seems to dream (2d) of an elysium wherein disease did not intrude. The swineherd tells of the blessed Syrian Isle over beyond Ortygia (Fig. 1). Neither famine or disease enter there, but when men grow old

Apollo with his silver bow and Artemis with her arrows gently remove them from life. I suppose this is what the divine pair will have to do for our sanitary Utopia when we have prevented all preventable disease. Some arrangement will have to be made to get people out of this troubled world, if gland rejuvenescence reaches its goal. It is singular that at the beginning we pinned our hopes largely to fumigation. Since history began smoke has arisen at altars both of religion and of science to drive away the devil and his works. It is still seen. Ever since Homer's day, and very likely before, sulphur was used for it. The smell at least is miraculous, and we are depending more and more on cleansing—on asepsis, but that, too, was the idea of Odysseus after the slaughter of the suitors. The hall in which they perished, the tables, walls and floors were spattered with the blood of the unfortunates and at dawn he had their bodies dragged out and stacked up in the yard and he set the maids to sponging and scrubbing off the gore and, "bring me brimstone, a resource against evil, and, old one, bring me fire in order that I may smoke the room with the sulphur" (2e).

A recent commentator (3) goes so far as to say the religious value which we are entitled to attach to instances of purification in the Homeric poems is extremely small. The Achaeans, even Penelope, do not seem usually to think it is religious, but a matter of cosmetics, tidying up; it is for appearance sake often they wash their faces and hands at feasts and even at sacrifices. In the days when I was young and bath tubs were scarcer than they are now in country districts, the bath Saturday night seemed really something of a ritual and to us boys unnecessary and annoying, but I am convinced our mothers' chief idea was cleanliness, yet there was something else, too. They put on their cleanest linen and brightest ribbons for church going, even that was only unconsciously a ritual and it really seems as though that might have been the Homeric feeling to a large extent. The lustrations, purifications, were in largest part esthetical. Some religious ritual was mixed with it and sanitation seems to have come last. When scabies and cholera seemed more largely to have visited the unwashed people must have got it in their heads the gods, who sent plagues to punish mankind, must be pleased with cleanliness and angered at filth and when epidemics were abroad this doubtless was especially kept in view, but for the most part it was kept in the background. The nurse evidently wanted (2f) Penelope to wash her face before she went into the presence of the suitors and we see it was because she wanted her to look her best, but Penelope, sorrowing for her absent lord thinks it is not worth while. One is rather surprised that the critic here makes a note that neither thinks of any religious reason for her to wash or not wash her face. However, Professor Gillies is right. Why did we begin to do it? At the bottom of this lies much which is important for us to know. If Penelope bathed and put on clean clothes before her vows to the gods and made Telemachus do so, too, she was but a forerunner of the mothers in my young days, for it may have been as true of her as of them that it was only incidentally a ritual. It was often omitted. Week day nights for prayer meeting the ceremonial of the bath was omitted, but it was said of an ancient friend of mine, who after a long and pious life built a house with all the modern conveniences, that he declared, when the building was handed over to him in the beginning of the week, he could hardly wait for Saturday night to take a bath in the tub. With Penelope and Telemachus purification became a custom, a habit, and it would seem as though its sacred affinities became a tradition more or less at first and finally the tradition nowadays seems to have been lost both for the Sabbath and salvation.

What Did the Indians Know About Medicines and Healing Treatments?

LESTER G. HERBERT
Auburn, N. Y.

(*Concluded from page* 24)

Boneset.—Used by all the tribes as a remedy for fever and colds.

Joe pye weed.—Used for difficult urination.

Jalap.—The Mexican Indians used the root as a drastic purgative.

Cranesbill.—Used in diarrhea, and by the Cherokee in decoction along with chicken grape as a mouth wash in thrush.

Bowman's root.—Employed internally as an emetic and externally as a poultice for swellings.

Grindelia.—Used variously in decoction for colds, consumption, colic, and as a wash for saddle galls and sores on horses' backs.

Witch hazel.—Used in infusion as a remedy for bruises, piles, and hemorrhages.

Hepatica.—Used as a tea or chewed for coughs, and together with walking fern in decoction as a remedy for snake dreams.

Cow parsnip.—Variously used for fainting, convulsions, intestinal pains, and as a poultice for boils.

Hops.—Fruits used in a tea for fever and abdominal pains; the chewed roots, occasionally with roots of ground cherry and meadow anemone, were applied to wounds.

Rattlesnake fern.—The bruised root was applied to cuts.

Sweet scented waterlily.—Preparations of the rhizomes were used for leucorrhea and suppurating glands.

Blue cohosh.—Variously used as a parturient, antirheumatic, febrifuge, etc.

Pipsissewa.—Internally, as a tonic and diuretic; externally, for open sores.

Water hemlock.—The roots were eaten by such as desired an early demise.

Black snakeroot.—A remedy for rheumatism, disordered menstruation, slow parturition, and bites of poisonous snakes.

Kinnikinnick.—The inner bark of this dogwood was employed in a smoking mixture, also as an emetic and in the preparation of black and scarlet dyes.

Yellow puccoon.—Used as a tonic, stomachic, and in the treatment of ulcers and sore eyes; also as a yellow dye.

Waterleaf.—A remedy for internal pains.

Cassine.—The leaves of this shrub were the source of the ceremonial "black drink" of the aborigines, who claimed it restored lost appetite, strengthened the stomach, and gave them agility and courage in war.

Blue flag.—Used as a remedy for gastric disturbances, earache, sores, and bruises.

Red cedar.—Variously employed as a remedy for headache, cough, colds, cholera, and as a diuretic and nervine.

Indian tobacco.—The dried leaves were smoked as an emetic.

Canada moonseed.—The rhizome and roots were used for scrofula and sore mouth.

Indian pipe.—The juice mixed with water was applied to sore eyes.

Tobacco.—The leaves of all native species were smoked, placed in the cavities of teeth for toothache, and in the hollows of the neck with oil and soot for cough.

Prickly pear.—The pith was used in the smoke treatment for sore eyes.

Ginseng.—Variously used for headache, cramps, female diseases, and, with red paint, as a love charm.

Poke root.—The root was used as an emetic and antirheumatic, the berries for a red stain.

May apple.—The rhizome and roots were used as a cathartic.

Seneca snakeroot.—Used in the form of infusion of the leaves for sore throat and in decoction as a remedy for coughs and colds and rattlesnake bites.

Solomon's seal.—The bruised root was applied as a poultice to swellings.

Wild black cherry.—The inner bark was used in infusion for soreness of the chest and as an application to sores.

White oak.—The bark of this and other oaks was used for diarrhea.

Castor oil bean.—The Maricoba tribe prepared earache drops from the seeds.

Wild roses.—An eye wash was made by steeping the roots in warm water.

Rumex.—The root and green leaves were variously prepared for treating hemorrhages of the lungs, sores, boils, wounds, etc.

Blood root.—Used as a red dye and love charm.

Scullcap.—In decoction as an emmenagogue and for numerous other ailments.

Spigelia.—Valued as a vermifuge before the discovery of America, also used as a sedative and diaphoretic.

Dandelion.—The powdered leaves were used in dressing fractures and bruises.

Bethroot.—A remedy for nosebleed and female disorders.

Hemlock.—The finely powdered bark was used to prevent chafing.

Cat tail.—The down as a preventive of chafing, the roots and ripe blossoms for scalds, the roots with the white bases of leaves for cramps.

Slippery elm.—Inner bark used as an expectorant and laxative, also cooked with animal fats in rendering out the grease, to prevent rancidity.

American hellebore.—New England Indians used the rhizome and roots as an ordeal in the selection of their tribal chiefs.

Culver's root.—Used in decoction as a purgative.

Cascara sagrada.—Used by the northwestern tribes as a purgative.

Sarsaparilla.—Used as an alterative by the Mexican Indians.

Krameria.—Used as an astringent by Indians of Texas and Mexico.

Aconite.—The leaves of a native species were applied for neuralgia and headache.

Red baneberry.—Used in decoction for gastric pains.

Aletris.—Used in decoction as a stomachic, tonic, and emmenagogue.

Pulsatilla.—Used as a counterirritant in rheumatism and neuralgia and as a love charm.

Bearberry.—Used in a smoking mixture and in decoction for pain in the back.

Artemisia.—An incense for exercising evil powers and in decoction for colds, worms, and other ailments.

Trailing mahonia.—In decoction as a stomachic.

American wormseed.—As a tea for painful menstruation.

ANIMAL DRUGS

Rattlesnake.—Variously prepared as a remedy for consumption and rattlesnake bite.

Pig.—The snout and blood were employed for snake bites.

Beaver.—The preputial follicles were used as an emmenagogue.

Cricket.—As a remedy for dysuria.

Lizard.—In decoction for bodily pains.

Spider.—Spider's web was applied to cuts as a styptic.

Owl.—The feathers were used as a remedy for loss of flesh.

The oils and fats of the buffalo, bear, and other wild animals were used as liniments and as ointment bases.

MINERAL DRUGS

These include red ochre mixed with fat for sunburn, slaked lime for gunshot wounds, woodashes for inflammations, and red clay for inducing sterility.

The Indians had a more extended acquaintance with the materials of medicine than has generally been believed. While some of their practices were shamanistic and a number of their remedies worthless, they employed many drugs of real value. Among the drugs which they used the following are officially recognized in the present editions of either

the *United States Pharmacopœia* or the *National Formulary:*

Seneca snakeroot, pleurisy root, poke root, yellow dock, jalap, blue flag, beth root, geranium, American hellebore, black snakeroot, golden seal, bloodroot, Virginia snakeroot, May apple, pint root, aletris, lady's slipper, angelica, Canadian hemp, spikenard, Canada snakeroot, trailing mahonia, blue cohosh, purple cone flower, Culver's root, cascara sagrada, sarsaparilla, wild black cherry, slippery elm, prickly ash, sassafras, dogwood, wahoo, butternut bark, white oak bark, rhatany, blackberry root bark, yerba santa, jimson weed, bearberry, witch hazel, pipsissewa, arbor vitæ, grindelia, lobelia, boneset, scullcap, pulsatilla, life root, verbena, elder flowers, hops, vanilla, pumpkin seeds, larch agaric, and turpentine. A number of others have appeared in former editions of these works.

From the Red Man of this continent, our forefathers gained knowledge of many of the uses of these drugs which has been passed down to the present generation as a valuable heritage.

Contributors to the Science of Medicine

Ephraim McDowell

Of the three outstanding pioneers of American surgery William Beaumont, J. Marion Sims, and Ephraim McDowell, the latter was most essentially the frontier practitioner, now rightly accorded the honor so long withheld from him or disputed, the "father of ovariotomy," Ephraim McDowell has now fully come into his own.

He was descended from north of Ireland stock, his greatgrandfather coming to Pennsylvania in 1729. In 1737 Ephraim McDowell, his greatgrandfather, with his family moved to Virginia. Ephraim McDowell was born on November 11, 1771, the ninth of eleven children and the sixth son. In 1783 the family removed to Kentucky where his father became one of the judges of the First District Court and in Danville, Kentucky, Ephraim McDowell spent the working years of his life.

In 1793 he went to the University of Edinburgh after receiving the best education that those early times and frontier conditions could provide. During his university career anatomy and surgery appealed to him especially, but for internal medicine his enthusiasm was lukewarm. It is even said that he characterized it as more of a curse than a blessing to the human race, while surgery he declared to be "a certain branch of the healing art." At Edinburgh he came under the influence of John Bell, the brother of the yet greater Charles Bell, the discoverer of the respective functions of the anterior and posterior roots of the spinal nerves.

McDowell, although an earnest student, is said to have left Edinburgh without taking a degree. Upon this point Gross writes: "I am not able to say, from the facts before me, whether Dr. McDowell was graduated from Edinburgh or not. His brother, Colonel McDowell, states that he was, and in this opinion he is joined by his son, as well as by his nephew, Dr. William A. McDowell. My belief that he did not take a degree in Scotland is based upon three facts: first, that no diploma of the kind has been found among his papers; second, that Dr. Samuel Brown, his classmate at Edinburgh, solicited him, after he had attained his eminence in his profession, to permit him and his friends to draw up an account of his cases in ovariotomy, in Latin, in order that it might be sent to Edinburgh, to secure him a degree; and third, that in 1825 the University of Maryland conferred upon him the degree of Doctor of Medicine, a circumstance which would hardly have happened had he been a regular graduate."

It may be taken for granted that he did not receive his degree from Edinburgh. In 1795 he returned home and began the practice of medicine at Danville, Kentucky. Of his contemporaries in the neighborhood two made great names as surgeons. Of these Walter Brashear in 1806 performed the first successful hip joint amputation. This was three years before McDowell's first ovariotomy. Brashear's case was not the first hip joint amputation as many believe, but it was the first successful one. Baron Larrey did the first seven years before. Dudley the lithotomist was another contemporary although he was considerably younger, and according to Gross was the first to ligate the subclavian artery and in 1841 successfully ligated the carotid artery. All this was prior to the age of anesthetics. He used boiled and boiling water in surgery. He died near Lexington, Kentucky, in the eighty-fifth year of his age.

Although McDowell began his career in a small frontier town his extensive and influential connections and the prestige of his foreign training and the absence of competition quickly brought results and for some time he was the best known surgeon west of the Alleghany Mountains. His practice is said to have extended over hundreds of miles and he had to travel to visit his patients under circumstances unknown to modern practitioners. There were no roads and no stage coaches and McDowell's professional calls were made on horseback through trackless regions. Indians and wolves were still a menace. Some of these calls, as Schachner points out in his biography of McDowell, meant absence from home for a week or more; in others, a surgical operation was involved. When it is borne in mind that anesthesia was unknown, that operations were done under conditions of the crudest simplicity, with no trained assistance of any description, it is wonderful to imagine how the old time frontier surgeons obtained the results they did.

McDowell performed all the operations of the day

and up to 1828, two years before his death, he had done thirty-two lithotomies without losing a life, among his patients being James K. Polk, who afterwards became President of the United States.

It is recorded that by preference he operated on Sundays, a practice that was in a measure followed by some of his successors in early Kentucky surgery. The reason given by some was that McDowell who was religious liked to have the benefit of the prayers of the church.

It was fourteen years after he had begun the practice of medicine that he set the seal to his fame by doing the first ovariotomy. He was called in to see a Mrs. Jane Todd Crawford, who lived about sixty miles from Danville, who was thought at first to be pregnant but as she had far exceeded the usual time it became evident that some abnormal condition existed and McDowell was sent for. When he had diagnosed the condition to his satisfaction he told Mrs. Crawford that if she consented he would endeavor to perform an operation which had never been attempted previously, for a case which was universally regarded as hopeless. Mrs. Crawford, who was as courageous as McDowell, accepted his advice and promptly appeared in Danville for the experiment as she termed it. For a description of the operation there is the direct statement of McDowell himself which was unearthed by Gross. The following is the account:

"My nephew, Dr. James McDowell, whom I had brought up, had graduated a few months before this time in Philadelphia, and had commenced business as my partner. Being in delicate health at the time, it was my intention to remove to the country in the spring, or as soon as I could establish my nephew in business. From the time of Mrs. Crawford's arrival he had made frequent attempts to prevent me from operating; but, finding my determination was fixed, he agreed to be present, but not until the morning I operated, and as my partner, to assist; for should the patient die, the responsibility was all my own; should the patient live, it would assist him in his outset in business.

"The day having arrived, and the patient being on the table, I marked with a pen the course of the incision to be made; desiring him to make the external opening, which, in part, he did; I then took the knife and completed the operation, as stated in the *Medical Repertory*. Although the termination of the case was most flattering, yet I was more ready to attribute it to accident than to any skill or judgment of my own; but it emboldened me to undertake similar cases; and not until I had operated three times, all of which were successful, did I publish anything on the subject. I then thought it due to my own reputation to throw all the light which I possessed upon diseased ovaria."

The features of the operation which Schachner thinks should be emphasized are these:

1. It was performed without anesthetics, antiseptics, trained help, or any operative accessories save the simplest domestic utensils.

2. The incision was made on the left side and nine inches in length, parallel to and three inches from *musculus rectus abdominus* presumably over the most prominent part of the tumor.

3. The tumor was freely movable, with a pedicle of sufficient length to enable ligation before the evacuation of its contents, or the delivery of the sac.

4. After opening the abdomen, the successive steps of the operation were: a. The ligation of the Fallopian tube and pedicle near the uterus. b. The evacuation of the contents, which were described as a "dirty gelatinous looking substance." c. The extraction and removal of the solid portion. d. Replacing the intestines that escaped with the opening of the abdomen and remained exposed until the removal of the solid portion. e. Draining the peritoneal cavity by turning the patient on her side to allow the escape of blood. f. Closure of the abdomen with interrupted sutures, allowing the ligature of the pedicle to pass out at the lower extremity of the wound.

5. Time of operation about twenty-five minutes.

6. The tumor was partly cystic and partly solid, the cystic element weighing fifteen pounds and the solid element seven and one half pounds, a total of twenty-two and one half pounds.

7. In five days he "found the patient engaged in making up her bed," and in twenty-five days she returned home.

There are eight cases of ovarian tumor operated upon by McDowell of which notes exist; four of the patients were white and four negresses. Five of these cases were complete operations, and three were incomplete. There was one death as the result of the operation. In a letter on the Crawford case McDowell said: "Since that time, 1809, I have operated eleven times and lost but one patient."

While attempts have been made by surgeons of several Enropean nations to deprive McDowell of the honor of first doing an ovariotomy, and while a certain amount of confusion exists as to the details, it is universally conceded now that to him belongs the fame of being the "father of ovariotomy" and to some extent of abdominal surgery.

No doubt it was largely because of the fact that McDowell lived in a frontier country on the fringe of civilization that made ovariotomy possible to him. He himself, a frontier man, selfreliant in a high degree, and living among a selfreliant, sturdy and free people, he had opportunities for pioneer surgery denied to the conservative cautious surgeons of towns. If he had not met such a woman as Mrs. Crawford his opportunity might never have come and their names will go down to posterity linked together as responsible for ovariotomy.

McDowell is described as being nearly six feet in height, erect, and inclined to corpulency, with a florid complexion and lustrous black eyes. He was very strong and agile, entertaining and possessed of a ready wit and humor. In his relations with his professional associatés he was modest and generous, but although "he did unto others as he would they should do unto him," the treatment he received from them was by no means of this kind. They were as a rule carping critics of his ability and work.

McDowell was not a rich man but was very well to do. As was the custom in his day, he owned a farm managed by an overseer and where he bred fine horses and swine. It may be said that he earned very good fees. In the Overton case, one of McDowell's ovariotomies at which General Andrew Jackson was

present, he stipulated for a fee of five hundred dollars, but it is said received fifteen hundred dollars from the grateful husband. Gross refers to this "as the largest fee ever paid in this country for a surgical operation."

When McDowell was thirty years of age he married Miss Sarah Shelby, the daughter of Isaac Shelby, Kentucky's first governor. Six children were born to this union, two sons and four daughters.

Towards the close of his life he conceived the idea of a country home to which to retire. According to some accounts he did not live to see the house completed; other accounts say that he spent the last few years of his life there. He gave this country home a Scotch name, Cambuskenneth, after the old Abbey of Cambuskenneth near Stirling. He never forgot Scotland, the Scotch blood in his veins was stimulated by his sojourn in Scotland and his walking tours in that picturesque and romantic country imbued in tradition.

The exact date of his death is not known. Some believe that he died on the evening of June 20, 1830, others give the date of his death as the evening of June 25, 1830. Schachner says, "As a discrepancy exists both as to the dates of his birth and his death, we may be permitted to add that so far as our study of the subject goes, a decided preponderance of the evidence favors November 11, 1771, as the date of his birth, and June 20, 1830, as the date of his death." He was fifty-nine at the time of his death, and his remains were interred in the family burial ground of the Shelbys, at Travelers' Rest, about five miles from Danville. In 1879 his remains were removed to what is now McDowell Park, formerly the old Danville Cemetery, which was given by the citizens as a site for the erection of the memorial monument. This occurred through the activity of the Kentucky State Medical Society.

Many of the pioneers of medicine and surgery, among whom Beaumont, McDowell and Marion Sims are supreme examples, were general practitioners in out of the way country districts. As said before this circumstance was in their favor as they were untrammelled by the conservatism and tradition which is apt to surround medicine and surgery in towns even in this enlightened age. Also their opportunities for original surgery, at any rate, were in pioneer days more numerous by far. The honor due to the surgeons of those times was that like Beaumont, McDowell and Marion Sims they saw their opportunities and seized them. It may be mentioned that Jenner was a country practitioner and that Sir James Mackenzie, who died recently, lived the greater part of his life as a general practitioner and worked out amid the arduous duties of his practice, his revolutionary views of the heart and its diseases.

The frontier surgeon, Ephraim McDowell, blazed the trail for those who have made such marvelous progress in abdominal surgery, and we may all be deeply thankful that he was a frontier surgeon or ovariotomy would not probably have come so soon nor would abdominal surgery be in the satisfactory position that it is in at the present time. The schools, although they may teach much, often at the same time tend to kill initiative. The difficulties which McDowell and frontier and country practitioners of the past times met, only served to put them on their mettle and bring out anything great that might be in them. The luxury so to speak which surrounds medicine and surgery nowadays is enervating, perhaps, rather than invigorating and stimulating.

Alcoholism in Byzantium.—Surrounded by the vineyards covering the slopes of the Hellespont, the Propontis and the Bosporus, Byzantium was always intemperate, said Professor Anselme in his recent paper before the Société Française d'Histoire de la Médecine (*Æsculape,* May, 1925). Theopompus and Phylarcus dwell upon the large number of inebriates to be found among the Byzantines. "These inebriates," says the latter, "live in taverns and rent their lodgings with their wives to strangers. They cannot bear to heâr the bugle call to war, even in dreams." Christian Byzantium was not less sober than pagan Byzantium and the large cities of the Grecian Empire followed suit. Drunkenness was a vice of so great extent that its consequences were more or less remote were known even to persons ignorant of medicine. Among disturbances attributed in those days to alcoholism were heaviness of the head, amblyopia, gout, tremors, paralyses, jaundice, apoplexy, epilepsy, disorientation, and dulling of the mental processes and loss of acuteness of intellect.

At various times the civil and religious authorities took measures to check alcoholism. But all their regulations seem to have had little effect, and alcoholism was many times the cause of bloody riots. Drunkenness, common among the lower classes, was by no means rare in other classes of society. A number of high functionaries, patriarchs and even churchmen were addicted to drink. But, in spite of the examples that he quotes, Professor Jeanselm states that the conclusion must not be drawn that drink was the rule among the higher classes of Byzantine society. Many of their rulers were exemplary in their conduct, and of the seventy-eight sovereigns who occupied the throne of Byzantium only ten were notoriously intemperate. After the taking of Constantinople, alcoholism continued. From their contact with the Greeks the Musselmans gave themselves over to drunkenness, in spite of its ban by the law of the prophet.

Bleeding a Military Punishment Among the Romans.—In a work, State of Gaul in the Fifth Century; Extract from the Memoirs of Uribald, published in Paris in 1805, is to be found a curious passage describing bleeding inflicted as a common punishment for certain Roman soldiers. "It is necessary to class bleeding among corporal punishments, a bizarre custom, which we have witnessed. It consists in opening a vein of the offender and drawing therefrom some drops of blood, as one would treat a bedridden patient. Opinions differ as to the origin of this curious custom. According to some, the offender is treated in this way because a cowardly act is so opposed to the military spirit that it can be looked upon only as a symptom of illness. According to others, it is to make the guilty one lose from his ignominious breast a part of that same blood which he has refused to shed for his fatherland. Aulu-Gelle who lived about the year 130 of our era, also that this is an ancient custom in military discipthat is to say three centuries before Uribald, says line."—Translated from *Æsculape.*

MEDICAL MEN AS POETS

A large number of members of the medical profession have been poets of considerable lustre. Dr. Charles L. Dana, himself endowed with high literary gifts, has collected and published in book form poetical works written by medical men containing one hundred and fifty-seven names. A French author has published a list even longer. It might be thought that poetry and medicine were not compatible and this view is largely borne out by history. The great poets who were medical practitioners or engaged in scientific medicine are few. Goethe and Von Haller, perhaps, were the only ones who were at the same time in the first rank of poets and distinguished in science. For the most part medical men who were also great poets were only medical men incidentally and little or not at all concerned with the practice of the healing art.

The present poet laureate of England is a doctor of medicine but can hardly be ranked with the great poets. Oliver Wendell Holmes was a great prose writer and composed good poetry and was in addition a distinguished physician, and the same remark may be made of S. Weir Mitchell. Schiller was an army doctor, but gave up this position as soon as he could. John Keats qualified but practised so little that few persons are aware that he gained a diploma to practise. George Crabbe, the poet of the peasant and of nature, according to Byron "Nature's sternest painter but the best," practised medicine for a short time and then forsook it for the church. Robert Southey was a medical student, and Coleridge dabbled in medicine, while it is not known whether Oliver Goldsmith was authorized by law to practise medicine or not. The unhappy Francis Thompson, author of *The Hound of Heaven,* spent eight years as a medical student. Rabelais practised as a doctor at a time when those who took holy orders were also physicians. Mark Akenside, of Newcastle-on-Tyne, was a poet of sorts. Francisco Redi and Bellini were physicians and poets of a high order. Tobias Smollett, whose verses are greatly overshadowed by his prose, was a ship's surgeon.

In more recent times Thayer, of Baltimore, has excelled in poetry, while Sir Donald MacAlister has translated German into English and Scots verse and Russian and modern Greek into English and old Scots verse, and some of the Czechoslovakian dialects into English and Scots verse with equal facility. The busy physician or surgeon has little time to spend on the making of poetry, and perhaps flies to it rather as a distraction and a relief for an overstained nervous system.

Recently Dr. Spencer Michael Free, F.A.C.S., has published poems that he has written in the interludes of a busy practice during the past few years, *The Human Touch and Other Poems.* These poems are marked by sentiment, realistic descriptions of men, scenery and things and enlivened by the spice of wit and humor. Also it may be said that they possess much literary merit. Among the medical poets of this country Dr. Free deserves a place.

CARDIAC RHEUMATISM IN CHILDREN

Heart disease was found to be the chief cause of death in the general registration area of this country in 1924, according to statistics, accounting for 176,671 fatalities, a slight increase over those of the preceding year. Heart disease generally, or at any rate very largely, begins in childhood in the form of cardiac rheumatism and could be prevented no doubt to a very considerable extent.

Dr. Llewellyn J. Llewellyn delivered recently in London the presidential address before the Section of Balneology and Climatology, Royal Society of Medicine. He took as his subject The Rheumatic Diathesis and dwelt especially on the cardiac rheumatism of children. He believes that the insidious cause of rheumatism affecting the heart in children is one of malnutrition of the cardiac wall. He submits that the insidious onset and often afebrile course of cardiac rheumatism, and alike the site and character of the muscular and fibromuscular lesions, are compatible with their metabolic and noninfective origin; that the primary change is one of cardiac malnutrition, arising on a subthyroidic substrate, reinforced by a vitamine deficient diet and recurring vascular stasis in the coronary arterioles. For the subthyroidism and assumed instability of the coronary circulation preclude speedy and efficient oxidation of lactic acid and other fatigue products elaborated during cardiac activities.

Muscular exhaustion induces acidosis and acidemia and these conditions exist in cases of acute rheumatism preceded by overfatigue. The guiding principle of Llewellyn's theme is that there is a diathesis or constitutional predisposition which renders certain persons liable to socalled rheumatic affections. The problem of heart disease in children is still unsolved. Although it is known that acute rheumatism is responsible for much of it, it is not known how acute rheumatism is caused and as the effective way to

prevent heart disease in children is to prevent acute rheumatism, the solution of the problem appears to lie in discovering means for preventing this disease. Llewellyn suggests that certain factors enter into the causation of rheumatism and that the soil is one of the most important, if not the most important, of these factors. His views are refreshingly out of the common, and as he has made a life long study of rheumatism in its various forms, they are worthy of careful consideration.

CANCER

What volumes we have of statistics pro and con for the increase in incidence of cancer, and what an awful waste of time and money goes on in their compilation and distribution.

What matters it whether cancer is increasing—we know it is not decreasing, and we know that its victims are a host. What we want to know are the conditions which induce it and its more immediate cause. There are cities in this country which publish monthly their socalled normal rates for smallpox, but we trust we will never become so dulled by its very frequency that we will have a normal rate for cancer and be only interested that the deaths do not exceed this limit.

We are entering, apparently, on the understanding of a new phase of the etiology of disease—the realm of the double agent, or, more likely, triple agent. We have had single agents, as the typhoid or the tubercle bacillus working in nonimmune tissues, and the double agents of fatigue, cold, or injury plus such a bacterial agent. There would seem to be also a virus working with ultravirus and, possibly, these assisted by metabolic mistakes over a long period. Cancer research seems to be tracking a double agent to its lair, but, since cancer is a disease of civilization, there must be some general fault of hygiene leading, in most cases, to the rooting of the more specific agents, just as dental caries has its origin in unsuitable diet. It is in this underlying condition, rather than in viruses and ultraviruses, that we should be most concerned.

The possibility of the cultivation and observation of tissues outside the living body is the most significant finding in medicine since the discovery of bacteria and of their causal relation to disease and will, undoubtedly, prove a key to the door, or one of the doors, of the cancer mystery, for these tissues can be subjected to various conditions, organic and inorganic.

Since cancer seems to be connected with parasitism of some sort, it is not unlikely that the race will, in time, acquire some immunity, just as it has for tuberculosis, for we know that the tide of tuberculous invasion has been gradually declining through the development of antituberculous agencies in the body rather than out of it. Cancer develops at an advanced age, but we do not as yet know in how many persons who do not succumb to the disease the causal agents may, as in tuberculosis, be at work at a very early period of their existence.

THE ADVANCE OF PLASTIC SURGERY

The war gave an immense impetus to the use of plastic surgery. Up to 1914 while the method was employed in civil life, it was not used as a means for repairing industrial injuries to the extent that it might have been. Now it appears to be coming into vogue for both cosmetic and strictly utilitarian purposes.

One of the most earnest and persistent advocates and practitioners of plastic surgery in this country is Dr. J. Eastman Sheehan, of New York, who has written a book on plastic surgery of the nose. This book, published recently by Paul B. Hoeber, Inc., New York, is a valuable testimony to the skill and ingenuity of the author in remedying many of the malformations or disfigurements of the outer nose, and a splendid example of the medical bookmaking art. Dr. Sheehan's book and those published within the past three years by Mr. Harold D. Gillies, of London, and Mr. Pickerill, of New Zealand, convey a good idea of how the specialty of plastic surgery is progressing.

In the preface to his book Dr. Sheehan pays a well deserved tribute to Mr. Gillies who, it may be remembered, was mainly responsible for the evolution of marked advances in the surgical methods of facial repair at the hospital established at Sidcup near London during the war. In most of the larger medical schools in this country departments of plastic surgery have been established and are doing excellent work. At St. Louis Hospital, Paris, an international clinic of otorhinolaryngology and faciomaxillary surgery has been established.

Plastic surgery has just been referred to as a specialty and if it is not generally so regarded by the medical profession, it seems that the time is fast approaching when it will take its place among the already long list of specialties.

An underlying motive for the introduction of plastic surgery was the desire to make use of the material of the body itself for its own repairs. It has been shown that this can be done successfully to the limited extent to which the method has as yet been put. This success opens a much wider field and the use of plastic surgery may be extended to the repair of parts of the body hitherto not subjected to this form of treatment.

The war taught us that plastic surgery was invaluable under the conditions then prevailing and since then it has been shown that in civil life this mode of repairing the visible areas of the body has a large field for its work. The future of plastic surgery is highly encouraging and it is certain that its scope of usefulness will be greatly enlarged.

TABOOS

"Provision for the adequate and temperate expression of sex is a necessary concern of every people." So says a student of the sex problem and the statement seems sensible on paper, but how is this pleasant state of affairs to be brought about? The author of this declaration does not make clear how it is to be done. There being no such provision made collectively (and there is not likely to be any) the "people" make provision individually and to a larger extent than has been supposed. Besides the agelong, deplorable outlet supplied by the prostitute, there is the practice of masturbation to fall back upon.

Until recently masturbation has been considered comparatively rare and confined chiefly to children. Moreover, it has been looked upon as a sin of the first water and a practice most detrimental to health. Eleven societies are hard at work solving the sex problem. One of these, the Bureau of Social Hygiene, in making a study of the sex life of the average woman, discovers that two thirds of unmarried college bred women have practised masturbation and one third of them, at the average age of thirty-seven, still continue this expression of sex. How naughty and how natural! Nor is it likely that they are different from their sisters who have not sojourned in college nor "worse" than those of a previous time.

Among normal boys and men who do not find other sources of sex expression the number who masturbate or have done so to some extent probably runs in the neighborhood of one hundred per cent. Even among animals (other animals we should say) at least domestic animals and wild animals in captivity, the practice prevails.

Reconstructing our quoted first sentence we can say that the expression of sex has been a necessary concern of every people and they have made provision in their own way and as best as they could. Probably they have solved the problem as well as it is likely to be solved.

By agelong public opinion the practice of masturbation is a vice and a sin, though, by private opinion, it seems to be considered neither the one nor the other. According to the advices from the group of college women, those who have masturbated are healthier than the others, as are also those who still continue the practice. Moreover, those who began early in life are no worse off than those who started after they had reached the age of eighteen.

Casting off agelong prejudice, we fail to see any essential difference physiologically between autoerotic and erotic practices, and pathologically safety is very much on the side of the former. The prejudice dates back to a very early date when the welfare and even survival of the tribe depended on having all possible population and when it seemed, in the wisdom of the elders, that it was a sin against the tribe and, hence, against the tribal god to waste seed in any but procreative channels. The spill of spermatozoa according to the manner of Onan came under the same tribal interdict, and the person who was so antisocial fell under the curse of the deity. The extension of this latter practice, which prevails among nearly all intelligent married persons today, to those who, in this twentieth century, need this or other means of limiting offspring, is opposed by a few truly fossiliferous individuals because the law that applied well enough among a primitive people struggling against slavery or extinction by war and pestilence, is looked upon as equally applicable to an age suffering from overpopulation, especially with overpopulation by the less intelligent.

The patients who come to the physician because of masturbation or because of onanism are those who are suffering because of mental states affecting the body begot of the old taboo, and not on account of effects of the practices themselves. The physician can cure them only by reassurance that they are neither sinful nor vicious and that they are in very excellent company in these practices. Instead of being a "vice," or a "sin," it is a means of saving a great many from the sin of both male and female prostitution and from gonorrhea and syphilis and their dire results on self or others.

THE NEW SOCIETY OF HEALTH

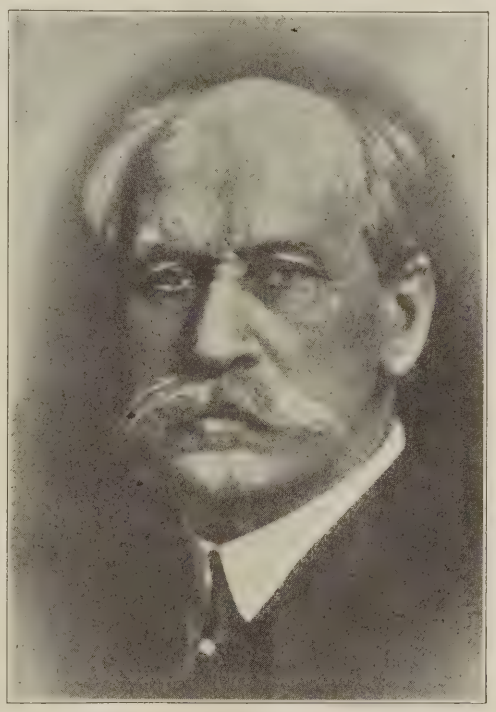
The New Society of Health, sponsored by Sir Arbuthnot Lane and of which he is president, was publicly ushered into the company of societies at a luncheon given to the founders by the Aldwych Club in London on December 11th last. It may be remembered by our readers that Sir Arbuthnot Lane explained the purposes for which the society was organized at a luncheon given in his honor by Dr. William Seaman Bainbridge in New York recently. At the luncheon in London the Earl of Oxford and Asquith, one of the founders. described the *raison d'être* and the aims of the society. Among those present were distinguished politicians, well known business men and leaders of the medical profession.

Obituary.

FRANCKE HUNTINGTON BOSWORTH, A.M., M.D.

D. Bryson Delavan, M.D.
New York

Dr. Francke Huntington Bosworth, son of Daniel P. Bosworth, a merchant, and Deborah Wells Bosworth, both of New England origin dating back many generations, died at his home in New York October 17, 1925. He was born January 25, 1845, in Marietta, Ohio, where his schooldays were spent and where he also attended Marietta College from 1858 to 1860. At the outbreak of the Civil War young Bosworth at once enlisted and saw active service in West Virginia under General Rosecranz. Having served his term of enlistment, he entered Yale College in the Junior class, graduating in 1862, with a group of associates, several of whom in later years became distinguished members of the New York Academy of Medicine. After graduating he again enlisted. His regiment was sent to the Peninsula and there he again saw active service, especially in repelling the raids of General Morgan. Having completed his military service he came to New York and matriculated at Bellevue, graduating in 1869 as valedictorian of his class. After serving the usual internship at Bellevue he entered into active practice in New York City and soon became interested in the study of the diseases of the upper air tract. In 1871 he was appointed lecturer upon this subject at Bellevue, and in 1881 was made full professor. When in 1898 that school united with the Medical Department of the New York University, Dr. Bosworth continued in his position as professor, retaining it until his final retirement from active work.



FRANCKE HUNTINGTON BOSWORTH

The career of Dr. Bosworth was marked by extraordinary and untiring industry. Enthusiastic in the development of the department of his choice, he gave to it the full devotion of his life. His days, spent in laborious office and dispensary work and in teaching, were followed by his arduous literary labors carried far into the night.

He distinguished himself as a writer, a teacher, and a practitioner, but it is upon his eminence as a pioneer contributor to the pathology of laryngology and to the practical application of his advanced ideas that his fame will endure. His theses and published articles, covering a long period of years, were numerous, comprehensive, and valuable. Possessed of unusual literary ability, his style was clear and forceful. The many new suggestions which he advanced were upheld with the full courage of his strong convictions, not seldom against adverse but, as time proved, mistaken criticisms. In discussion he delighted in drawing forth the arguments of the opposition, not so much for the pleasure of successfully refuting them, as for the profit of recasting and correcting such of his own views as might be imperfect before finally committing them to print. He had well learned the secret for the successful launching of a new idea, namely, that to cause it to be accepted it must first be intrinsically good, and then brought vigorously before the world by persistent, oft repeated attacks through the media of the journals, the lecture, and the society debate. With untiring industry and rare singleness of purpose he worked for the advancement of his chosen art.

Early in his career he entered upon the field of publication and in 1879 issued a *Handbook Upon Diseases of the Throat for the Use of Students.* In 1881 appeared his *Manual of Diseases of the Throat and Nose.* For the next ten years he was busily engaged in the preparation of his greatest work—a treatise in two large volumes on *Diseases of the Nose and Throat.* These volumes appeared, respectively, in 1890 and 1892. Meanwhile, the importance of the nasal region, never before fully appreciated, had impressed Dr. Bosworth so forcibly that in this publication he changed the sequence of the title of his work, and for the first time in history, instead of using the time honored title—Throat and Nose—reversed the order. Finally, in 1896, he issued his *Textbook on Diseases of the Nose and Throat,* a book which for many years enjoyed the popularity which it deserved.

The treatise of Dr. Bosworth, in two volumes, published in 1890, was a monumental contribution to laryngology. Together with the pioneer work of Dr. J. Solis-Cohen, of Philadelphia, published in 1878, and that of Sir Morell Mackenzie which appeared in 1882, it marked an epoch in the advance of the specialty. Works had been published by the early laryngologists in various countries of Europe, some of them of distinguished merit, but it remained for Dr. Solis-Cohen to present the first really comprehensive treatise upon the upper air passages ever issued. It dealt with the whole realm of the subject, and was beyond question a determining influence in establishing laryngology upon a definite basis. Dr. Mackenzie's classical work which followed in 1882 was different in style from that of Dr. Cohen, but scholarly, practical, and complete, it embodied the wide and long continued experience of the most accomplished laryngologist of his time.

The therapeutics of the specialty, theretofore chao-

tic and eminently crude, were by Mackenzie reduced to a scientific basis. Many of his remedies and methods have never been improved. Finally, with the appearance of Bosworth's great work, the specialties of laryngology and rhinology were thoroughly placed before the world.

It is interesting and significant to note that this great scientific accomplishment was attained by three English speaking men, two of whom were Americans.

In the study of rhinology, Dr. Bosworth became more and more impressed with the eminent importance of the nasal cavities. Upon the early recognition of this he greatly prided himself.

His success as a teacher was attested by the large numbers of students who sought his instruction at Bellevue, over a period of many years. His enthusiasm was genuine and infectious, and through his disciples as well as through his writings served to carry far and wide the knowledge of the new science. The vast numbers of patients who resorted to the Bellevue clinic gave abundant opportunity for observation and investigation, which Dr. Bosworth zealously improved.

In the course of Dr. Bosworth's writings many new ideas were presented, most of them original, some the practical application of the suggestions of others. While distinguished in many directions he will always be best known by his notable contributions to rhinology. Prior to his time the nasal region had been largely ignored.

The causes of mouth breathing, the physiology and pathology of the sinuses, the existence of remediable nasal obstructions, received little or no attention, even among the leaders of laryngology. The distinguished American observer, Catlin, had long before recognized the existence of mouth breathing and had warned of some of its evil results, but neither he nor any one else had clearly recognized its causes or suggested means for their relief until Dr. Edward Woakes, of London, published some ideas upon what he called "necrosing ethmoiditis," and advocated the removal of some forms of obstruction by the use of the saw. As commonly happened in those days of the tardy recognition of good work, the ideas of Dr. Woakes were not generally accepted. Dr. Carl Seiler, of Philadelphia, a man of great discernment and originality, who first used the perforated nasal splint afterwards perfected by Asch, attempted to remove septal obstructionc by means of a metacarpal saw. Before the days of local anesthesia this was difficult and unpopular. Bosworth also had been studying the matter. He found that many serious conditions of obstruction were caused by septal ridges and spurs. No other treatment of them was practicable but their mechanical removal. Certainly at this particular time fortune smiled upon him, for coincidently with the idea which had come to him cocaine was introduced, he devised his admirable little saw and, with it and local anesthesia, the riddle of nasal obstruction due to septal spurs was solved. True, better methods have been found since then. Bosworth's method was not perfect, especially as little heed was paid to preservation of the mucous membrane; but the results he obtained by it in those early days were often remarkably good. Through his eloquent advocacy and through the oft repeated visible evidence of the value of the method, its popularity was almost instantaneous. Through this and through his other valuable contributions, the attention of the world was directed to the nasal region. Brilliant scientists like Jarvis, Harrison, Allen, Bryan, John Mackenzie, Roe, Shurly, Daly, and others in this country; Moure, of Bordeaux; Zuckerkandl, of Vienna, and others of the continent of Europe and in Great Britain, took up the study, and the science of rhinology was triumphantly launched.

One of the most interesting phases of Dr. Bosworth's life was in connection with the New York Laryngological Society, the oldest society of laryngology in the world. Dr. Bosworth was one of its founders in 1873, and one of its most enthusiastic supporters until in 1886 it was merged into the Section of Laryngology and Rhinology of the New York Academy of Medicine.

Dr. Bosworth was an Episcopalian and in politics a staunch Republican. Regarding him from the human side, he was eminently blessed in the possession of a fine constitution and in the enjoyment of excellent health. His general interests were wide. He had many acquaintances among actors and dramatists. In his earlier days he was fond of horses and gained much diversion from daily drives along the uptown Speedway behind his handsome fast trotter. Among the first to take up golf as an exercise he played with vigor for many years, although never highly expert. His interest in fine arts was discriminating and accurate. He was a member of the Union, the Metropolitan, the Players, and the Social Arts Clubs, and for many years a familiar figure at the University Club.

Dr. Bosworth was a Fellow of the New York Academy of Medicine, the American Medical Association, the American College of Surgeons, and of various other medical societies. He was a charter member of the New York Laryngological Society in 1873, and a founder of the American Laryngological Association in 1878, and its president in 1883, and of the American Climatological Association. He received distinguished recognition abroad, and was an Honorary Fellow of the British, French, and German National Laryngological Societies. At the Eighth International Congress, held in Copenhagen in 1884, and at several subsequent congresses, he made notable contributions.

He married on September 21, 1871, Miss Mary Hildreth Putnam. Mrs. Bosworth died about fifteen years ago. Two children survive him, a son, F. H. Bosworth, Jr., professor and dean of the School of Architecture in Cornell University, and a daughter, the wife of Hon. Walter R. Herrick, of New York.

It may be that in the time to come Dr. Bosworth will be known by some one of his lesser gifts to medicine, but in company with Solis-Cohen and Sir Morell Mackenzie he, more than any who had gone before, gathered together the disjointed and scattered fragments of laryngological knowledge, developed the science of rhinology, and, welding all into a perfectly coordinated form, established them as definite and distinguished departments of medical science.

He was a man of ideas; a dreamer of dreams, dreams in which he himself believed; strong enough and earnest enough to make his dreams come true, and to impress the truth and the value of them upon the world.

The Health Resort of Nauheim

ELSA DENHAM
New York

Nauheim, one of the most important of the German health resorts and world famous for its treatments for heart troubles, lies in the shadow of the Taunus Mountains, about forty-five minutes from Frankfort on Main, and is easily reached by the main traffic railway lines from all the seaports of the Continent.

Universally known as the leading resort for the cure of heart disorders, due to its springs, which are perhaps unique in their curative properties, this spa is visited annually by some forty thousand persons, and summer and winter patients afflicted with heart disease flock to this delightful resort in search of relief and cure.

As one leaves the station, Nauheim seems to unfold like a picture book. Going down the hill towards the main street, one sees the fountains rising from the gardens that surround the bath establishments.

Here the Great Sprudel shoots up, steaming, from a depth of over five hundred feet; the temperature of this spring is 30.5° C.; it contains two and sixteen hundredth per cent. salines, and 3,434 cubic centimetres of free carbonic acid.

Next to it, the Friedrich Wilhelm Sprudel, rising from a depth of six hundred feet, has a higher temperature, a larger percentage of salt and 4,451 cubic centimetres of free carbonic acid gas.

The Ernst Ludwig Sprudel, 687 feet deep, is similar to the Big Spring with, however, a slightly higher temperature.

Besides these springs, used essentially for bath cures, there are a number of other sources used for drinking cures; two saline springs, excellent in effect on the intestinal ducts, an alkaline acidulous spring, the waters of which are used in the treatment of catarrhs, and three iron springs used in the treatment of the uric acid diathesis. Some of these spring products make excellent table waters.

The outstanding feature of the three big springs in Nauheim, is the natural warmth of the water, which corresponds exactly with the temperature prescribed and required by most patients who resort to the baths. The water flows from the depth of the earth directly into the tubs; it is not pumped up and warmed artificially as is the case in many other resorts. The water is used immediately as it comes from the earth, and there is therefore no loss of heat or carbonic acid.

One of the factors that make Nauheim so important from a medical point of view is the unusually large number of different kinds of baths available and the fact that it is possible to grade the baths correctly with regard to the amount of salt, iron, temperature and carbonic acid required. Thus the baths may be adapted minutely to any degree of illness, and to the various different and individual requirements of those taking the cure.

The sprudel steam baths, the strongest carbonic acid brine baths of naturally warm water, popularly known as champagne baths, are only one of the many varieties.

There are the thermal sprudel baths; fountain or

Fig. 1.—The Kurhaus.

Fig. 2.—The Kurhaus in the Park.

spring baths, a milder, radioactive, nonsaline form; sprudel baths, as they come from the earth, and brine baths without carbonic acid. These are just a few of the many varieties of baths that Nauheim has to offer.

Not only diseases of the heart are treated at this famous spa. The waters and baths at Nauheim are taken also for gout, rheumatism, incipient arteriosclerosis, female troubles, spinal diseases, and disorders of the nervous system.

A curious feature at Nauheim is the series of graduation houses, where the water from the springs is used for certain healing purposes by passing it over high walls of blackthorn bush. Here people come to breathe the air which is strongly impregnated with ozone and this air is said to be as effective in cases of chlorosis as sea air. There is a rest garden near one of these walls where patients may lie comfortably in chairs.

The treatment of heart diseases, however, is Nauheim's specialty, and the fact remains that if patients will come to Nauheim in time many diseases of the heart may be radically cured, or, if not entirely so, they may be greatly relieved and the course of the disease checked to a large extent.

All of the installations necessary for the successful diagnosis and treatment of diseases may be found in Nauheim.

The bath establishments, of which there are four, are the last word in luxury and comfort. They are provided with lounging rooms, reading rooms, and individual dressing rooms adjoining each bath cell.

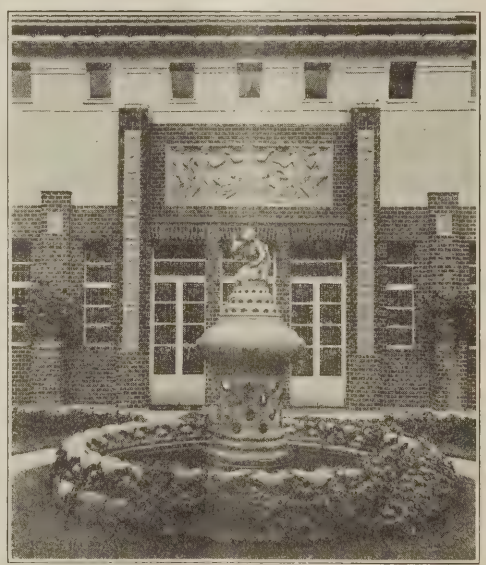


Fig. 3.—Entrance to one of the bathing houses

The pump houses are extensive modern buildings with every equipment required from both a scientific and a technical point of view. They comprise, besides the pump room proper, long, covered promenade lobbies, gargling rooms, a milk cure establishment and a bar where mineral waters are served.

The inhalatorium building is considered a model institution. In the rear of this building there are public inhalation rooms with Heyer's apparatus for open evaporation, five individual inhalation rooms on the Spiess system, von Hoessle's ideal apparatus, the Schnitzer apparatus, Goebel's duplex, the Unicum and Goebel's pneumatic machine. Carbonic acid inhalation is also provided. A radium emanatorium is in the north wing of the building. Radiation therapeutics, electric quartz lamps, solux lamps, spectrosol lamp radiation, Mebolit lamp and diathermal apparatus may be found in another building.

For purposes of diagnosis there are the latest medical appliances of all kinds, the most up to date x ray machines, electrocardiographs and sphygmographs. There is a medicomechanical Zander institute, with electric light, four cells, and alternating current baths.

Sand, mud and fango baths and packs may also be had at Nauheim.

The beautiful situation of the resort, on the slope of the Taunus Mountains, the fresh invigorating air, the large parks and woods, the almost country stillness, combined with all the comforts, conveniences and luxuries of a world renowned spa, make Nauheim not only a place for the sick but also a very popular resort for those enjoying good health who are seeking recreation.

The Kurpark, comprising an area of 469 acres, is one of the finest and largest parks in Germany. There are beautiful walks through idyllic groves and forests of mighty oaks, and the temples and shelters scattered here and there afford cover in bad weather.

The Kurhaus, the principal meeting ground for those taking the cures, lies high in the park, and has a fine view of the gardens and the spa region. It

contains two theatres, an excellent restaurant, a reading room, a billiard room and lounging room. Numerous entertainments are given here during the year.

There are eleven exceptionally fine tennis courts in the park. The golf links, with their pretty club house and restaurant, are situated a quarter of an hour's walk from the Kurhaus, in a charming part of the Frauenwald. The large lake, and the rivers Usa and Wetter offer good boating and fishing facilities.

An attractively situated trap shooting gallery has recently been set up on the Goldstein, five minutes walk from the railway station.

The neighborhood is rich in beauties of nature and historical monuments. Good railway connections and regular tours in comfortable motor buses offer ample facilities for visits to the Taunus and the Vogelsberg, to the numerous large towns in the vicinity and to the picturesque regions of the Rhine, the Main and the Lahn.

News Items.

Typhoid Carrier.—Thirty-three cases of typhoid, three of them fatal, have been traced by the Michigan State Health Department to a woman who assisted in serving a church dinner at Eaton Rapids, Michigan.

Prize for Essay on Tuberculosis.—A prize of ten thousand liras is announced for the best essay on the pathological anatomy, pathogenesis, or treatment of pulmonary tuberculosis, to be awarded by the Forlanini endowment. Eight copies of the study must be received by the Ospedale Maggiore at Milan, Italy, by December 31, 1926.

Mortality Statistics.—The Department of Commerce announces that in 1924, in the death registration area, there was a death rate of 11.9 per thousand of population, compared with 12.3 in 1923, 11.8 in 1922, and 11.6 in 1921. The rate for influenza decreased during the year from 44.7 to 19.6; and the rate for pneumonia decreased from 109 to 98.4. The rates for heart disease and cancer showed slight increases.

Doctor Green Honored.—A dinner was given at the Harvard Club, Boston, in honor of Dr. Charles M. Green, professor emeritus of obstetrics and gynecology at Harvard, on his seventy-fifty birthday. About two hundred and fifty pupils and former house officers attended. Dr. Frederick C. Shattuck, of Boston, was toastmaster, and addresses were made by Dr. Joseph B. deLee and Dr. Emilius C. Dudley, of Chicago, Dr. Barton Cooke Hirst, of Philadelphia, and Dr. John O. Polak, of Brooklyn.

Gifts and Bequests.—Montefiore Hospital of New York has received a gift of $50,000 from the Altman Foundation of B. Altman and Company.

Gifts of fifteen hundred Christmas boxes, including cash, were made by John Doukas, a Greek confectioner of New York, as a share of his profits for the year. Several hospitals were included among the twenty-five organizations receiving these gifts.

One of the patients of the late Dr. E. Guernsey Rankin, a professor at the New York Homeopathic Medical College and Flower Hospital, has given the school a memorial check for one hundred thousand dollars. The College announces the completion of its endowment fund of two hundred and fifty thousand dollars.

The Eye, Ear, Nose, and Throat Hospital of New Orleans has received a gift of fifty thousand dollars from Mrs. John Dibert, which increases her gifts to the institution to the amount of one hundred and thirty-five thousand.

Princeton University has been granted one million dollars by the General Education Board, contingent upon its raising two million, for the purposes of research and advanced teaching in biological and physical science.

Hospital News.—Cook County Hospital of Chicago is starting work on additions which will give it a capacity of thirty-five hundred beds. The new accommodations will include an eight story children's hospital, with a minimum capacity of four hundred and eighty beds; a new men's building, seven stories, with a minimum capacity of three hundred. There is also to be a new morgue, and a new receiving building, with tunnel passages to all parts of the hospital. The cost of these improvements is estimated at two and one half millions.

St. Mark's Hospital of New York has purchased property on Eleventh Street, and work on an addition will start at once.

The French Hospital of New Orleans, which has been in operation sixty years, is remodeling its building and doubling its capacity.

The Charity Hospital of New Orleans has opened a new building for white women medical patients. This building will take care of one hundred and twenty patients, and cost about $335,000.

The Troy Hospital, Troy, New York, recently celebrated its diamond jubilee.

The Borough Park Maternity Hospital of Brooklyn has opened a three story fireproof addition.

The Coney Island Hospital is planning to double its capacity, and will add a nurses' home.

The Kings County Hospital will erect a new eight story building for gynecology and obstetrics, accommodating nearly four hundred patients.

A Chinese Hospital has been opened in San Francisco, built at a cost of two hundred and fifty thousand dollars. The four divisions of the staff are presided over by American educated Chinese physicians. The provisions are mainly for charity patients, and there is a free clinic.

The will of the late Rudolph J. Schaefer provides $50,000 for the Lenox Hill Hospital, of New York.

The will of the late Dr. William Carr provides some $20,000 for the Hospital for Ruptured and Crippled Children, New York.

The Free Hospital for Women, of Brookline, Massachusetts, has recently celebrated its fiftieth anniversary.

Personal.—Dr. Max Einhorn of New York has been elected corresponding member of the Société de Gastroenterologie de Paris.

Dr. Adolf Lorenz of Vienna has returned to America and resumed the practice of orthopedic surgery, at the office of Dr. Dexter D. Ashley, New York.

Dr. Louis I. Harris has been appointed health commissioner of New York City.

Dr. E. M. Bluestone, assistant director of Mt. Sinai Hospital, New York, has resigned to act as director of the Hadassah Medical Organization. This organization controls most of the medical work in Palestine and that locality.

Dr. Frederick W. Sears of the New York State Department of Health gave an address on Some Problems in Rural Hygiene, as one of the De Lamar lectures, at Johns Hopkins University.

Dr. William H. Humiston, clinical professor of gynecology at Western Reserve University Medical School, and Dr. John M. Ingersoll, associate professor of otolaryngology, have been made emeritus professors.

Dr. Maurice Ostheimer, who has been on the faculty of the University of Pennsylvania for twenty-five years as teacher of pediatrics, and also in practice in Philadelphia, has retired to his country home at Whitford.

Dr. Francis Carter Wood, of the Cancer Institute, New York, is in Europe studying the recent developments in cancer treatment.

Sir Frank Colyer, F.R.C.S., L.R.C.P., L.D.S., London, England, has joined the Board of Collaborators of the *Review of Clinical Stomatology*, the official organ of the American Stomatological Association. Dr. Colyer is a leading and active worker in stomatology in England and was president of the International Stomatological Association during the years 1911 and 1913.

Dr. Alfred J. Asgis will be in charge of the courses to be given at the stomatological school recently chartered by the University of the State of New York and functioning under the auspices of the American Stomatological Associaition. Due to these added responsibilities, Dr. Asgis has resigned from the Department of Gastroenterology of the New York Polyclinic Medical School and Hospital.

Society News and Notes.

The newly organized Pennsylvania Public Health Association, composed of officials engaged in health work, has had its first annual meeting, with election of the following members of the medical profession as officers for 1926: Dr. Charles H. Miner, president; Dr. Wilmer Krusen, vice-president; Dr. J. C. Vaux, second vice-president; Dr. William C. Miller, secretary and treasurer; Dr. J. C. Raunick, assistant secretary and treasurer.

Through the American Society for the Prevention of Cruelty to Animals it has been announced that at the next Westminster Kennel Club show, which will be its jubilee and the first annual one to be held in the New Garden, for the first time in this country, cups for uncropped dogs belonging to breeds heretofore shown cropped will be offered. Recently the American Veterinary Medical Association by resolution condemned cropping and voted in favor of non-cropping, stating that the former custom involved unnecessary cruelty and is a needless practice, contrary to the ethics of the profession. Cropping was abolished years ago in England as an act of barbarous cruelty.

* * *

At the joint meeting of the Physics and Radiology Section of the International Congress of Radiology held in London last July, it was unanimously resolved that an International Committee be appointed to consider the establishment of an x ray standard of intensity and an x ray unit. In order to give effect to this resolution, it was unanimously carried that the X Ray Unit Committee formed in February, 1923, be requested to communicate with the physical and radiological societies of the principal countries throughout the world with a view to the nomination by those societies of representatives to constitute such an International Committee.

The new officers of the American Public Health Association are: president, Dr. C.-E. A. Winslow; first vice-president, Dr. John A. Ayyot, Deputy Minister of Health of Canada; second vice-president, Dr. Max C. Starkloff, Health Officer of St. Louis; third vice-president, Dr. A. J. Chesley, Health Officer of Minnesota; Dr. Dublin was unanimously reelected treasurer. The next meeting of the association will be held in Buffalo in October.

* * *

The second annual dinner of the New York Alumni of the Sigma Xi (National Society for the Promotion of Scientific Research) was held at the Faculty Club of Columbia University on the evening of December 14th. The program was divided into two parts: a discussion of the responsibility of scientists in disseminating scientific knowledge to the public; and an experimental demonstration of recent advances in contemporary physics by the Physics Department of Columbia University. Among the speakers who took part in the first half of the program were D. S. Kimball, dean of the College of Engineering of Cornell University; Otis W. Caldwell, director of the Lincoln School, Columbia University; Franklin H. Giddings, professor of sociology and the history of civilization, Columbia University; and Watson Davis, managing editor of *Science Service*.

* * *

At a recent meeting of the Society of Medical Officers of Health of Great Britain, and at the final meeting of the Baby Week Summer School, the question as to whether or not advice on methods of birth control should be given at infant welfare centers was the topic for discussion. The consensus of opinion was practically unanimous against general advice on the subject at such centers, and a small number favored referring exceptional cases, where family conditions were known, either to a special clinic or to a gynecological department.

* * *

The Women's Foundation of Health, New York, has announced the awarding of a bronze medal in each state to a woman who has during the past year or years rendered the greatest service to women. This is to be known as the Agamede Medal; a national committee will then select from the group the one to whom a gold medal will be given. The women may be scientists, physicians, actresses, housewives, professional or business women, or women of wealth and social position who are qualified as nominees.

On Monday, January 25th, the Section of Anthropology and Psychology of the New York Academy of Sciences will meet. Earlier January meetings were that of the Section of Biology on January 11th, and of the New York Microscopical Society on January 15th.

* * *

The annual meeting of the New York Academy of Medicine was held on January 7th. After a business session, Dr. D. Bryson Delavan made an address on Early Days in the Academy, Dr. Samuel W. Lambert on Academy Activities in Our Present Building, and Dr. Linsly R. Williams on the Future Work of the Academy. Other January meetings at the Academy were those of the Section of Dermatology and Syphilis on January 5th, with presentation of patients from the Vanderbilt Clinic, the Skin and Cancer Hospital, and Fordham hospital; the Section of Surgery on January 8th, in which presentation of cases by Dr. Carl Eggers, Dr. Franz Torek, and Dr. Herbert Willy Meyer was followed by papers by Dr. Edward C. Davidson on Prevention of Toxemia in Superficial Burns, and by Dr. Meyer on Undescended Testicle. The new automatic electromechanical apparatus for transfusion of whole unmodified blood was demonstrated by Dr. A. L. Soresi. The Section of Otology met on the same evening, with demonstration of a new instrument for the treatment of OMCC with superheated air, by Dr. John Guttman; presentation of cases by Dr. Hugh B. Blackwell, and Dr. John McCoy, who also read a paper on Zinc Ionization Treatment for Chronic Discharging Ears and Allied Conditions. The Section of Neurology and Psychiatry met on January 12th, with case presentations by Dr. Byron Stookey, Dr. E. D. Friedman, Dr. Ira Cohen, and Dr. A. S. Taylor; papers were read by Dr. C. B. Masson on an Air Manometer for Spinal Manometric Tests; Dr. S. Silbert on a Method for the Study of Changes of the Size and Shape of the Ventricles in Brain Tumors; Dr. Wilder G. Penfield on Staining of Tumors of the Nervous System; and Dr. F. H. Pike and Dr. C. A. Elsberg on Intracranial Pressure and Susceptibility of Animals to Convulsive Seizures. The Section of Pediatrics met on January 14th. The papers of the evening were by Dr. Sydney V. Hass and Dr. Julius Blum on the Prophylactic Value of Older Plasma and Whole Blood of Convalescents in Measles.

* * *

The Clinical Society of the Jewish Memorial Hospital, New York, met on January 5th at the Dispensary Building. The scientific session was conducted by Dr. A. Greenberger and Dr. L. Neuwelt. Case reports were given by Dr. S. Weiss and staff, Dr. E. Bleier, and Dr. M. Seigalstein.

* * *

The Harlem Medical Association of New York City met on January 6th at the Ellsmere. A case report was given by Dr. Herbert E. Stein, and papers read by Dr. Sidney V. Hass on Celiac Disease; the Value of Banana in its Treatment; and by Dr. Jacob Sobel on Essential or Primary Hypotonia in Young Children.

* * *

The Eastern Medical Association held its stated meeting at the New York Academy of Medicine on January 8th. The papers of the evening were by Dr. Irving Roth on the Clinical Features of Cardiac Irregularities; and Dr. Cary Eggleston on Treatment of Heart Failure with Special Reference to the Use of Digitalis.

* * *

The Association of Italian Physicians in America held its stated meeting on January 8th at the New York Academy of Medicine. The papers of the scientific session were by Dr. Herbert Bergami on Problems of Present Day Traumatic Surgery; and Practical Therapeutics, by Dr. L. K. Neff.

* * *

The American Ethnological Society and the Section of Anthropology of the New York Academy of Sciences held a joint meeting at the American Museum of Natural History on the evening of November 23d.

* * *

The Pennsylvania Tuberculosis Society held its annual meeting at the Bellevue-Stratford Hotel, at Philadelphia, January 19th and 20th. The establishment of the eleven tuberculosis hospitals recently authorized was considered, and clinical programs were held at the Jefferson Hospital and the Henry Phipps Institute. In addition, papers were read by leaders in the field of tuberculosis work.

* * *

Among the speakers at the Women's Industrial Conference, held in Washington this month under the auspices of the Women's Bureau of the Department of Labor, will be Dr. Alice Hamilton of Harvard, and Surgeon General Cumming, of the Public Health Service.

* * *

The Interstate Postgraduate Association of North America will include Rome, Florence, Venice, Munich, Prague, Berlin, Amsterdam, Brussels, and other medical centres in its trip. Dr. William J. Mayo is president of clinics, Dr. Charles H. Mayo, general chairman of foreign assemblies, and Dr. George W. Crile, chairman of the program committee. Applicants must be in good standing in their state societies. Further information may be obtained from Dr. William H. Peck, the managing director, of Freeport, Illinois.

* * *

The Canadian Medical Association has appointed a committee to report on fakes, nostrums, and quackery, and to recommend suitable action by the association.

* * *

The Philadelphia County Medical Society has elected Dr. Moses Behrend, president; Dr. Frederick S. Baldi, vice-president; Dr. Henry G. Munson, secretary, and Dr. Edward A. Shumway, treasurer.

* * *

The members of the Sigma Phi Fraternity, in Southern California, celebrated the eightieth birthday of Dr. Richard S. Dewey, of Pasadena. Doctor Dewey was formerly in charge of the Milwaukee Sanatorium, Wisconsin, and before that, in charge of the Illinois State Hospital at Kankakee.

Book Reviews

ABDOMINAL SURGERY

Abdominal and Pelvic Surgery for Practitioners. By Rutherford Morison, Hon. M.D. and D.C.L., Hon. LL.D., M.B., F.M.C.S. (Ed. and Eng.), Consulting Surgeon Royal Victoria Infirmary. London and New York: Humphrey Milford, Oxford University Press, 1925. Pp. 203.

This little book is written with a definite purpose by one of the great surgeons of the day and, moreover, it seems to have fulfilled its purpose. The introduction is a model of what introductions should be as it explains clearly why conditions as regards the medical profession are as they exist today, and why for this reason the patient should depend more on the general practitioner than he does depend at present. Also Mr. Morison recommends that the general practitioner should fit himself to be a reliable counsellor of his patient as to the need for operation, the kind of operation and the choice of operator. As Mr. Morison remarks pertinently operators are like golfers. Many can play at golf, after prolonged instruction and practice, but few can ever play golf. Unless the golf is in, it can never come out. There are many operators but few surgeons.

The author realizes fully that the condition of the medical profession has changed and is changing and that the status of the medical man is undergoing something like a revolution, but while comprehending all this he points out that the public is so dissatisfied now with the chaotic and unwholesome state of affairs in the medical profession, that his belief is that the time is ripe for "the doctor" to come into his own again by realizing his responsibilities, as the guide and friend of the patient.

In this country and in Great Britain radical changes into methods of medical and surgical practice have been and are being introduced so that Mr. Morison's comments apply to conditions in America to some extent. In the body of the book the author gives useful advice drawn from a wide experience of the practice of abdominal and pelvic surgery in war and peace. Throughout the book the need for promtitude and skill in operating is emphasized.

PULMONARY TUBERCULOSIS

La Tuberculose Pulmonaire. By Leon Bernard, Professeur à la Faculté de Medecine de Paris, Second Edition. Paris: Masson et Cie., 1925. Pp. 400.

The first edition of this book was well received and was soon exhausted. In the second edition, which is much larger than the first, the author has taken into consideration the newer advances in phthisiotherapy and the remarkable progress made in France regarding the social aspect of the disease. He gives full credit for these improvements over the former deplorable condition in France, to the *Comité National de Défence Contre la Tuberculose* and expresses grateful appreciation for the invaluable help which has been given to this committee by the Rockefeller Foundation, saying eloquently, that the hearts of France owe to the latter foundation an unforgettable gratitude. The book, which had its origin in the lectures delivered by Prof. Bernard before and after the World War at his clinic at the Laennec Hospital and at the *Ecole de Médecine,* is now completely rewritten.

In the first chapter is given an excellent description of our present conception of the infection and immunity of tuberculosis. Bernard makes no less than five divisions of the chronic form of tuberculosis: first, the extensive ulcerative and caseous types; second, the same type but localized; third, the extensive ulcerative fibrinous type; fourth, the localized fibrinous type; and fifth, the tuberculous bronchitis, in which he includes the tuberculous emphesema. Of the acute types he makes six divisions: the first he calls caseous pneumonia; the second, galloping phthisis; the third, the granulated type of tuberculosis; the fourth, typhoid bacillosis and septesimic phthisis described by Landouzy. As fifth he mentions the cortical pleuritis; and lastly, the general pleurisy or primary tuberculous pleuritis. By the latter he means the pleurisy à frigore, mentioned in the old classics. The descriptions of these types are interesting and thorough.

In his chapter on the stethoscopic signs of tuberculosis, he makes the following significant statement: "We now know that the beginning of tuberculosis in childhood is due to a first infection and that this primary invasion results in sclerotic pulmonary ganlion which contain the bacilli. When in adult life this tuberculosis developes it may be due to a renewed activity of these bacilli or to a new additional infection." The stethoscopic signs are carefully described with characteristic French minuteness.

Chapter 5 deals with the prognosis of pulmonary tuberculosis, and Bernard concludes by saying that the physician in his endeavor to come to a decision must, without neglecting any of the physical signs and symptoms, also resort to a careful blood pressure examination and cutaneous reaction. This latter means of determining a prognosis would seem to the reviewer of little importance since cutaneous reactions, no matter how carefully made, do not reveal either the extent, locality, chronicity or acuteness of the infection.

Interesting are Bernard's conclusions concerning tuberculosis and maternity. He says when a prospective mother is in the latter stages of pulmonary tuberculosis and all indications are for a fatal termination because of the tuberculous disease, the mother should be carefully watched during pregnancy, which should not be interrupted, so that at least the life of the child may be saved. He is convinced that the justification of interrupting pregnancy in tuberculous mothers is exceedingly rare. Of course, he enthusiastically supports the practice of separating the child from its tuberculous mother immediately after birth, and he quotes the statistics that the mortality of the babies separated from their mothers immediately is 5.7 per cent., while among those who were only taken from their mothers later and evidently infected, it was 7.6 per cent. Under modern treatment of tuberculosis nothing new is offered. It is rather surprising that aside of artificial

pneumothorax the author has nothing whatsoever to say on the surgery in tuberculosis. Pneumolysis, phrenicotomy, and thoracoplasty receive no mention whatever. This is a serious omission, otherwise the book can be highly recommended to physicians and students as a guide in the study of clinical and social aspects of pulmonary tuberculosis. The discussion of the social phase of course is of particular interest to the conditions in France.

DRUGS ACTING ON THE HEART

Les Médicaments Cardiaques. Par le Docteur L. Cheinisse. Paris: Masson et Cie, 1925. Pp. 179.

In this small volume Dr. Cheinisse summarizes the action and uses of the important drugs that act on the heart. The book is planned for the general practitioner. Chapters are devoted to digitalis, strophanthus, as well as the lesser drugs of the digitalis group, calcium chloride, caffeine, camphor, adrenalin, atropine, eserine, and quinidine. For each medicament the author gives the indications, contraindications, methods of administration, and action. The presentation is clear and accurate, and shows a familiarity with the important literature. The book should be useful as a brief and up to date summary of the uses of the potent drugs that act on the heart.

EXPERIMENTAL MORPHOLOGY

Handbuch der biologischen Arbeitsmethoden. Unter Mitarbeit von über 600 bedeutenden Fachmännern herausgegeben von Geh. Med.-Rat Prof. Dr. Emil Abderhalden, Direktor des Physiologischen Institutes der Universität Halle a.d. Saale. Abt. VIII, Methoden der experimentellen morphologischen Forschung, Teil 1, Heft 4. Experimentelle morphologische Untersuchungen. Ernst Leupold-Würzburg: Lipoid-, Glykogen- und Pigmentstoffwechsel. Berlin-Wien: Urban & Schwarzenberg, 1925. Pp. 791-940.

In this number of this encyclopedic work the experimental morphologic methods of investigating the metabolism of the lipoids, glycogen and the pigments found in the human body are described in minute detail. It is a highly technical publication of value only to the physiologist.

MEDICAL RESEARCH IN JAPAN

Transactions of the Japanese Pathological Society. Volume XIII. The Thirteenth Annual Scientific Session Held in Tokyo, April 1, 2 and 3, 1923. Published by The Japanese Pathological Society. Editorial Office: The Pathological Institute of the Imperial University, Tokyo. Pp. x-235.

This report contains one hundred and forty-three different articles on various subjects, such as studies on ascariasis and other parasites, spirochetosis icterohemorrhagica, tsutsugamushi, bacteriological studies, histological studies, tumor transplantation, and many others too numerous to mention in a short review. It is of interest to pathological laboratories but of very little interest to the general practitioner.

LOCAL IMMUNIZATION

Immunisation Locale. Pansements Specifiques. Par A. Besredka, professeur a l'Institut Pasteur. Paris: Masson & Cie, Editeurs, 1925.

The object of this short treatise is to present, as the author says, a different path than that which has been followed up to the present on the way to immunization. The idea of local immunization, which practically means that there is not necessarily a production of antibodies, is still in a rather nebulous stage, although definite facts speak in its favor, certain phenomena can be explained on no other hypothesis, and the practical application has been made in various instances of vaccinotherapy. To illustrate the main idea, Besredka has chosen a number of typical infections involving the skin and the intestinal canal, respectively. These are anthrax and malignant pustule, staphylococcus infections, dysentery, and typhoid states.

Medicoliterary Notes.

Los Angeles has a complete clinic on wheels for its school children. It is operated by the Board of Education's Department of Health. This travelling clinic has a complete set of optometrist's and dentist's tools and fixtures, and all other equipment for promoting general health among school children. In such a way two physicians and a nurse can supervise the welfare of hundreds of children daily.

* * *

Robert Quillen, humorist and author, according to the *New York Times,* has erected a monument in his front yard to Eve, the first woman, and the townspeople are horrified. Beneath the inscription, "In Memory of Eve, the First Woman," is a carved apple, with a twig and one leaf. In an editorial in his own newspaper, answering the criticism of his neighbors, Quillen wrote: "Eve was a distant relative of mine, on my mother's side. The family has always been proud of her. She was the first lady of the land and the reigning beauty of her time."

* * *

An interesting article on Sex in Children, by Jessie Taft, Ph.D., director of the Child Study Department of the Children's Aid Society of Pennsylvania, is reprinted from *The World Tomorrow* in the *Mental Hygiene Bulletin* for November, 1925.

* * *

Under a recent decree of the communal administration of Ghent, Belgium, marriage fees have been tripled in cost. Heretofore one hundred, fifty, or twenty-five francs have been the amounts required to be donated to the commune, according to whether the marriage was in the socalled first, second or third class. The newly stipulated fees are exactly three times larger than the former ones. A marriage service *de luxe,* including a small orchestra in addition to an organ, will cost six hundred francs.

* * *

An innovation in the teaching of a specialty, namely, its presentation by means of the motion picture film, has been undertaken by Dr. J. F. Montague, of 540 Park Avenue, New York City. Dr. Montague is able to show in this way, in a comparatively short time, all the interesting cases he has seen during the past nine years. This is one of the interesting features of Dr. Montague's motion picture course in proctology.

* * *

The League of Nations' Secretariat has been asked to ban all spirit writing. This is probably the strangest of the many strange things that the League has been asked to do. A letter containing the request is said to have been received from a New York business man, declaring that "brain enslavement" caused by spirit writing and other kinds of messages from the dead is a cause of many great evils, one of the greatest of which is that all American "courts of justice" are under the control of spiritism. The letter states that "the American people need help from the whole world to bring an end to something which is really the greatest crime against civilization."

* * *

In his annual report for 1924, recently issued, Rear Admiral E. R. Stitt, Surgeon General of the Navy, states that there was less sickness in the navy during that year than in any since the War. The death rate from diseases

was unusually low, being only 1.78 in 1,000 of personnel. The year 1922 was the only year in which the death rate was lower than these figures show. There were no deaths from typhoid or paratyphoid fever. Pneumonia was the principal cause of death, totalling thirty-three, compared with twenty-nine in 1922.

* * *

The mysteries of crowd psychology are being constantly brought before us. Several years ago in Berlin a play was produced at one of the theaters without attracting any undue attention. This winter it has been revived, and on the first night caused a riot, which included catcalls and hisses and finally a walkout on the part of half of the audience and an attack on the manager and actors by the other half. The police were called in to quell the disturbance. The play is *Die Kleine Sklavin,* by Dietzenschmidt, and deals with the downfall of a girl of fourteen. The Church and moral welfare societies are reported as taking steps against the continuance of the play; but the critics, although condemning it as a proper performance, are unanimous in predicting a long run for it because of the remarkable acting of the leading players, one of whom is Erika Meigast, a girl in her teens who plays the title rôle. She is generally conceded to be Germany's greatest coming actress.

* * *

Hamlet in modern costume was such a success in England that *Faust* was given in twentieth century attire during the Christmas holidays by the Birmingham Grand Opera Society, one of the largest organizations of its kind of the British Isles. The plot was slightly modified to suit the caste and the occasion.

* * *

The tuberculosis clinic for children, under the management of the Yale School of Medicine and the New Haven Dispensary, has recently issued its first report. The clinic has been operating since December, 1924, and is the only out patient tuberculosis clinic in the country dealing exclusively with children under six years of age. The report shows that 250 children are now being cared for by the clinic, in support of the viewpoint that the successful combat against tuberculosis lies rather in the protection of the young child than in the care of the adult after he has developed the disease.

* * *

Dogs—pedigreed, mixed breeds and "mutts"—have increased in number so greatly and so rapidly in Berlin that they are becoming a nuisance on the streets, according to some visitors. In an effort to reduce their numbers, and also to add to the city budget, the administrative committee of the City Council has presented an order, which, if passed, will increase the tax on dogs to $17.50 a year. In 1924 there were 205,000 licensed dogs in the city, an increase of fifty per cent since 1920.

* * *

On December 24th the new Peabody Museum of Natural History of Yale University was formally opened and dedicated. One of the most interesting features is that the exhibits are arranged to illustrate the evolution of the forms of life from the ameba to man. This is the work of Prof. Richard Lull, director of the Museum. He has limited his specimens to those fitting into the chronological life of this planet. A feature of the exhibits is the collection of the late Prof. Othniel Charles Marsh, which includes probably the most noted collection of fossil vertebrate animals in the country.

* * *

That color blindness is responsible for many railroad crossing accidents has been discovered by the Swedish State Railways. They have, therefore, decided to install bluish white lights in place of green ones, and others of a particular shade of red, which is supposed to be most easily recognized by automobile drivers. It has been arranged that these lights flicker at different speeds when a train is coming and when the crossing is safe, so that when drivers cannot distinguish the colors, they can tell by the flickering when a train is approaching.

* * *

A new and valuable use for ultraviolet rays was revealed to the Academy of Inscriptions and Belles Lettres on December 23d by M. Samaran, according to the *New York Times.* M. Samaran says that he has discovered that it is possible to read the original texts in palimpsests through use of the rays. Many books and scrolls were erased by scribes during the Middle Ages in order to write in them the records and chronicles of their own times. Thus many priceless documents were lost, among them the missing books of Livy, a contemporary of Christ. By inspecting the palimpsests with the ultraviolet rays, the inferior layers can now be easily read, where before chemicals had been tried and failed to produce results.

* * *

Because of the large number of persons killed and injured in the Fourth of July celebration, 1925, Dr. Hugh S. Cumming, Surgeon General of the United States Public Health Service, recommends in his annual report a renewal of the campaign for a "safe and sane Fourth." The report states that in thirty-six states 111 persons were killed and 1,030 injured in this manner. Of the injured 148 will probably lose one or both eyes. In many cases death was found to have been caused by fireworks popularly considered "harmless," such as sparklers, blank cartridges, cap pistols, skyrockets, small firecrackers, and Roman candles.

* * *

Clemence Dane, the well known English writer and playwright, in a recent interesting article on the past year's fiction in the *Manchester Guardian,* choses as the outstanding novels of 1924 Hugh Walpole's *Portrait of a Man with Red Hair;* Robert Nathan's *Son of Amittai,* published in this country as Jonah; and Naomi Mitchison's story of fifth century Greece, *Cloud Cuckoo Land.*

* * *

As an aid in mosquito control during the coming year, the State Board of Health of Texas announces plans for the establishment of local hatcheries for the propagation of top minnows. This is being made possible through the cooperation of the game, fish, and oyster commission, which will furnish these minnows for breeding purposes, the only cost to the localities being that of transportation and the cost incident to shipping. The State health officer has recently advised all cities and communities of the State desiring breeding stock to notify the game, fish, and oyster commission of their needs as soon as possible, in order that sufficient time may be allowed for the propagation of enough minnows for use in stocking all local streams, ponds, tanks, and other places with standing water.

* * *

Among the ten outstanding magazine articles for December, selected by the Library Service Bureau of the Franklin Square Subscription Agency of New York City were The Biology of Health, by Raymond Pearl in the *American Mercury,* and The Chaos of Modern Marriage, by Dr. Beatrice Hinkle in *Harper's Magazine.* Another December article of unusual interest is Life Versus Lives, by Havelock Ellis, the fourth in the *Forum's* War and Peace Series. Isaac Goldberg has in the same issue of the *Forum* an account of the Youth of Havelock Ellis. Other recent magazine articles of interest to physicians are: Blundering Parents, Wayward Children, by Florence Hull Winterburn, in *Current History* for November; The Human Will, by A. Wyatt Tilby, in the *Edinburgh Review* for October; The Fallacies of Current Cancer Research, by Dr. Herbert Snow, in the *Contemporary Review* for October; I Saved My Life by Disobeying the Doctor, by Allan Swinton, in the *Cosmopolitan* for December; The Amazing Importance of Posture in Children, by Harriet Wilde, in the *Designer* for December; and Aseptic Surgery in the Fourteenth Century, by Dr. G. D. Hindley, in the *Nineteenth Century* for October.

* * *

Among recent publications of interest to the medical profession are the following: *Battling the Criminal,* by Richard Washburn Child (Doubleday); *Manual of Injurious Insects,* by Glenn Herrick (Holt); *Psychological Healing,* by Pierre Janet (Macmillan); *Almost Human,* by Robert M. Yerkes, the report of a study of a colony of apes at Habana (Century); *Theories of Instinct,* by E. C. Wilm (Yale University); *Food, Nutrition and Health,* by E. V. McCollum and Nina Simmonds (the authors); *The Doctor Looks at Biography,* by Dr. Joseph Collins (Doran); *School and Home,* by Angelo Patri (Appleton); *Psychology and History,* by Harry Elmer Barnes (Century); *Opium as an International Problem,* by W. W. Willoughby (Johns Hopkins); and *The Visiting Teacher in Rochester,* Report of a Study, by Mabel Brown Ellis (Joint Committee on Methods of Preventing Delinquency).

Abstracts from Current Literature

PEDIATRICS

Retropharyngeal Lymphadenitis in Young Children.—Herman B. Sheffield (*Archives of Pediatrics,* October, 1925) writes concisely his observations of fifty-nine cases of retropharyngeal lymphadenitis which came under his care the past winter when influenza was prevalent. Nineteen of the children had some time before been successfully operated upon for the removal of tonsils and adenoids. Dr. Sheffield says that he learned early to discourage surgical intervention even in apparently severe cases lest the disease terminate in Ludwig's angina. He also noted that marked swelling of the lymphatic glands followed in all cases in which surgery was resorted to early, often thereafter requiring repeated rather mutilating operations to effect a cure.

Miliary Tuberculosis in an Infant Twenty-eight Days of Age.—A case of miliary tuberculosis in a twenty-eight day old infant is described by Harry M. Gilkey (*Archives of Pediatrics,* September, 1925) who is inclined to think that living tubercule bacilli may be present in the fetus and newborn child without exciting histological changes and developing some time after birth may then give rise to characteristic tuberculous lesions. A true latent congenital tuberculosis would therefore be both probable and possible and perhaps a more common occurrence than is generally supposed.

Sweetened Condensed Milk as a Food for Infants.—A. W. Bosworth (*Archives of Pediatrics,* September, 1925) in a preliminary paper, makes some interesting observations about the value of sweetened condensed milk as a food for infants. Although the fat content is low as compared with breast milk, and the supply of vitamine C is probably low, the amount of sugar, protein, calories, vitamines A and B compare favorably. Lassalbliere (*Soc. Biol.,* 81, 1918) is quoted as saying that the method of preparing sweetened condensed milk brings about some chemical or physical change in the milk which cannot be duplicated by the simple addition of sugar to milk or evaporated milk. A table of a few experiments shows the greater pathological efficacy of sweetened condensed milk in comparison with evaporated and powdered milks; and the influence, but more feeble, of saccharose when added to unsweetened condensed milk. It follows that the mere presence of saccharose does not wholly explain the results obtained with the sweetened condensed milk.

Comparison and Interpretation on a Caloric Basis of the Milk Mixtures Used in Infant Feeding.—Grover T. Powers (*American Journal of Diseases of Children,* October, 1925) classifies milk mixtures according to the caloric value of the constituents without regard to water content and finds that the mixtures fall into seven groups. There is a table giving the composition of foods in gravimetric percentages. Fourteen interesting charts illustrate the following points:

The dilution of milk mixtures with water affects the calories per unit of mass, but not the percentage relationships of protein, carbohydrate and fat in the total calories.

The addition to milk mixtures of an energy yielding nutrient affects not only the total calories per unit of mass, but also diminishes the proportional representation in the total calories of the protein, lactose and fat.

The magnitude of any food component in a mixture, as expressed by its percentage representation in the total calories, is relatively increased by the removal or reduction of any other food component.

An energy yielding nutrient, if introduced in a ration fixed with relation to the other energy yielding components of mixtures made increasingly dilute with water, does not affect the representation in the total calories of the other components.

On the other hand, an energy yielding nutrient, if introduced in a ratio fixed with relation to the total constant volume of mixtures made increasingly dilute with water, brings about a reduction in the values of the protein, lactose and fat percentages of the total calories.

A great number of mixtures which experience has shown to be particularly successful in feeding infants fall into a majority group which approaches the caloric percentage pattern of the food mixtures in the sweetened condensed milk group; about sixty per cent. of the total calories are in whole milk and forty per cent. in added carbohydrate.

One third milk with five per cent. added sugar, and other somewhat less frequently used mixtures, have the identical caloric percentage configuration of sweetened condensed milk and of whole milk to which seventeen per cent. sugar has been added.

Human milk, cow's milk, whey, protein milk and skimmed milk are the most prominent representatives of the remaining five groups.

The Czerny-Kleinschmidt and Moro butter flour mixtures have the same proportions of the total calories in protein, carbohydrate and fat as has human milk.

It is a striking fact that the vast majority of successful milk mixtures used in infant feeding are unlike human milk, which stands apart from all other foods; indeed the popular mixtures are as unlike human milk as they are unlike unmodified cow's milk.

Concentrated Feeding.—Bela Schick (*Archives of Pediatrics,* June, 1925) advances the following indications for concentrated feeding: I. Healthy children; a, lowered instinct for food intake, impossibility of feeding in usual volume the required caloric value (premature child); b, high caloric feeding for fattening. 2. Nervous vomiting. 3. Pylorospasm. 4. Children with diseases associated with difficulty in feeding: a, diseases with lowered tolerance of the intestine, e. g., measles (in such cases we are at least able to supply the caloric value required for the basal metabolism); b, diseases without evident damage to the tolerance of the intestine, such as difficulty of feeding in functional disturbances (loss of consciousness or cloudy sensorium in diseases with high temperature—meningitis, typhoid fever, etc.), difficulty in swallowing (angina and other throat and nose infections), dyspnea (pneumonia, croup, etc.), cough (whooping cough, pneumonia), lack of appetite in different diseases (tuberculosis, influenza), infectious diseases of other origin (dysentery tetanus, etc.). 5. Children with disorders of water balance, such as cardiac insufficiency, nephritis, pleurisy, and bedwetting.

The Relation of Clean Milk to Progress in Infant Feeding.—John Lovett Morse (*Boston Medical and Surgical Journal,* October 15, 1925) says that the improvement in the methods of infant feeding since the early nineties has been as great as that in the milk supply. Hit or miss methods have gradually been replaced by rational procedures based on scientific knowledge. Proprietary foods have been more and more replaced by milk mixtures and the proprietary foods which used to be given mixed with water are now given mixed with milk. Milk now forms the basis of all foods for infants. It is true that no respectable cow would recognize many of the concoctions which are manufactured from it nowadays, but, nevertheless, the basis of them all is milk. Methods are continually changing, however, sometimes for the better and sometimes, it seems to some of us, for the worse. Nevertheless, whether the composition of the food is calculated in percentages or in grams of the different food elements or in ounces per pound of weight, whether it is given raw or boiled, acidified or alkalinized, at long or short intervals, milk is the basis and those who prescribe the food have, or think they have, a good reason for what they do.

Breast Feeding—Past, Present and Future.—Dr. Frank Howard Richardson (*Archives of Pediatrics,* October, 1925) tells of the Nassau County, L. I., demonstration that breast feeding was not only the most desirable form of sustenance for the young of the species (of course universally conceded before); but also that it was almost universally available. The data obtained were submitted to the Bureau of Statistics for evaluation. Some points elicited from the demonstration were, for instance, the decreased infant mortality in the breastfed group, as compared with those artificially fed; the decreased infant mortality of Nassau County for the period of the demonstration; and the diminution of morbidity in the breastfed babies studied—most marked in the gastrointestinal disorders, but also marked in the respiratory diseases; and in the infectious

diseases, especially whooping cough, measles, and chickenpox —three diseases, whose severity we have been almost completely powerless to check by any specific measures when once they do occur; and other points of much social interest, such as the fact that the American mother has the poorest records for maternal nursing. A gratifying result, according to Dr. Richardson, is that since 1924 (the demonstration had been made the previous year) appeals have come in for information as to what had been done, and for help in staging similar efforts elsewhere in the State.

Roseola Infantum.—John Zahorsky (*Archives of Pediatrics,* September, 1925) again calls attention to the disease peculiar to infants and possessing the following characteristics: the febrile course with sudden onset, the general symptoms, the crisis, the appearance of the rash, the convalescence; furthermore, its incidence during infancy, its noncontagiousness, its prevalence during all seasons, its independence of epidemics of rubella, and the freedom from sequelæ. In a further statement as to the incidence of this desease which is frequently mistaken for German measles he says that in the last fifteen years he has seen more than three hundred cases of roseola infantum. It is not an uncommon disease, he thinks, and believes many more cases occur, since the mildness of the symptoms in many infants does not alarm the parents sufficiently to send for a physician. It is almost exclusively a disease of the young child. Dr. Zahorsky urges naming this disease roseola infantum, a term that would be acceptable to mothers and would not cause confusion if applied to this definite clinical entity.

Radical Cure of Neuroticism in Children.—Clinical evidence to show that much of the neuroticism of children is psychogenic and can be reconditioned into happy usefulness by psychological means is not lacking, according to Tom Williams (*Archives of Pediatrics,* October, 1925) who also holds that no artificial methods like hypnotism, dream analysis nor set association experiments, are required to remove a child's phobia effectively; that the patient will introspect honestly if he knows that he will not be laughed at or blamed. But of his motivations the patient is not always aware, even when himself honestly introspecting. That is, when a mere desire animates him; one which is not a matter of conditioning at all, but which is of the primitive nature as seen in appetite for food, sex gratification, acquisition, fighting, affection, or movement, and worst of all, perhaps, in the struggle for air. When the impediments to these legitimate desires cause a conflict which is not frankly engaged in, secondary ruminations of a theoretical character may develop into a neurotic state. Taking one instance, a child had multiple tics which proved to be compensatory movements against a sense of guilt engendered by infantile jealousy of a younger brother. This was radically removed without recurrence fourteen years later. Without doubt physical conditions often have more bearing on the state of maladjustment than is usually known but experience has shown the tremendous importance of the psychological factor.

Bacillus Coli Infection of the Urinary Tract in Young Children.—J. Walter Carr (*Clinical Journal,* July 1, 1925) says that the one and only aim of treatment is to render the urine constantly alkaline and to keep it so for about a fortnight. It seems that the Bacillus coli cannot live in an alkaline urine, so that the object of treatment in Bacillus coli infection of the urinary tract is to convert the socalled alkaline tide into a continuous alkalinity. The salt commonly used for this purpose is citrate of potash. Large and frequent doses are essential if all the urine which is secreted is to be alkaline. For adults about a dram must be given at least every three hours, and for children even relatively larger quantities are necessary. During the first year of life a start may be made with five grains every two hours by day and every three hours by night, but this dose will probably have to be increased to ten and sometimes even to fifteen grains before the urine becomes constantly alkaline. After the first year still larger doses will probably be necessary. When given in these large amounts citrate of potash may cause some digestive disturbance, especially diarrhea, in which case bicarbonate of soda (or of potash) in the same doses may be tried instead. On the whole, the author says he has had the best results from giving the two salts together in equal quantities. In any event, whatever drug is used, it is essential that a sufficient quantity be taken to ensure that all the urine secreted is alkaline. A supply of red litmus paper should be given to the child's nurse or mother, and she should be instructed to test the urine each time it is passed. It should not be kept before testing, because, as already stated, it tends rapidly to decompose.

As soon as the urine has become constantly alkaline—it may take two or three days even when full doses of an alkaline salt are being given before this is attained—the temperature will almost certainly fall to normal and the general condition rapidly improve, but the alkalinity must be maintained, without exception, until the child has been free from fever for from seven to ten days, otherwise a relapse will almost certainly occur and the whole treatment have to start again *de novo.* Even after the temperature has been normal for a week or longer it is better gradually to diminish the quantity of the medicine than to discontinue it abruptly. It may also be wise to continue full doses of the alkali so long as pus cells are present in the urine, even if the temperature has been normal for more than a week.

Treatment of Constipation in Infancy.—J. Claxton Gittings (*Therapeutic Gazette,* October 15, 1925) says that while we are waiting for dietary changes to be effective, we must use certain laxatives. The simplest of these are normal saline enemas, gluten suppositories, mineral oil, and magnesia. Alternation is safer than the constant use of any one thing. A small bulb full (two ounces) of saline may be sufficient as an enema, repeated if necessary, or a larger amount (six to eight ounces) may be given through a soft rubber No. 20 French catheter with the baby lying on its left side and the buttocks elevated. The fact that large enemas may cause a tendency to syncope must not be forgotten. Gluten suppositories may be used in place of the bulb of saline solution. Mineral oil, with or without agaragar in one to two dram doses, is most useful, especially where the stool is of the dry "marble" type. Milk of magnesia in one or two dram doses usually is effective without causing pain.

For very constipated babies an occasional does of castor oil (one dram once or twice a month) with the mineral oil is permissible so as to insure a thorough evacuation. For older infants, six to eight months or over, ten to thirty drops of aromatic cascara may be used with mineral oil, in place of castor oil.

The use of even simple drugs and local stimuli always is to be deprecated. Nevertheless, when dietary corrections and exercise, fresh air and sunlight have failed to cure, therapeusis becomes essential.

When obstinate constipation persists beyond the eighth month in spite of mixed feeding, and without such causes as rickets, a gastrointestinal x ray is indicated to rule out a possible malformation.

Cerebral Degeneration in an Infant.—Norah H. Schuster (*British Journal of Children's Diseases,* July-Sept. 1925) tentatively presents the following case as a separate malady distinct from Wilson's disease and places her case from its resemblance in respect to ischemia, maldevelopment and degeneration with a group of two others referred to by D. Paterson and E. A. Carmichael in *Brain,* 1924, xlvii.

The family was composed of eight healthy children, ranging from twenty years, of which the one described below was the youngest. The second youngest, a Mongol, had died at the age of two and one half years. The confinement had been normal and the infant breastfed till four months old, and up to its final illness it had been healthy except that the mother reported restlessness at night, frequency of stools of normal appearance, and occasional twitching when teething. It had been wasting for six weeks. It was first seen at the age of five months, when it presented the symptoms which led to the diagnosis, was admitted to hospital, investigated and then discharged. At six months he was admitted to the Infants' Hospital, having got steadily worse, and he died three days later. At this time the child was in a wasted condition and weighed ten pounds three and one half ounces. He lay inert, with eyes open. He appeared to be blind, though the pupils reacted normally to light. He passed loose offensive stools, and took his food badly with occasional vomiting. There was asymmetry of the skull, the right side being higher than the left. The knee jerks were difficult to obtain. The Wassermann reaction was negative, and ophthalmological examination revealed nothing wrong with the fundus. The child slept little, but showed no fretfulness, and was altogether extremely limp until the last day, when he started "twitching." The temperature

varied between 100° and 104°, and pulse and respiration were irregular, perhaps because of the intestinal condition.

In examining the material yielded by the necropsy Dr. Schuster considered that there was not sufficient reason to class the case with Wilson's. First, the clinical picture was entirely different; this case presented no athetoid movements and no tonic spasms or rigidity, and the difference in age was, in effect, wide, because the disparity between the nature of the diseases of infancy and those of youth is considerable. Second, the pathological picture of Wilson's disease is not complete without cirrhosis of the liver, and this feature was entirely absent in this case. It would be more relevant to compare the pathology with that of encephalitis where the lesion is purely cerebral, but it is difficult to believe in such an infection occurring *in utero*, and there is no evidence of inflammation in the brain or membranes.

In comparison with Paterson's and Carmichael's cases, pathologically the essential lesion is the same, namely, a degeneration chiefly localized to the basal ganglia combined with excessive production of bloodvessels and neuroglia. The cortex presents a different picture, but it is apparently more a difference of degree than of kind. The absence of myelination and of pyramidal cells in the original cases shows a more complete degeneration, and is concordant with the severer changes in the putamen. The most important discrepancy is the total absence of round celled infiltration and meningeal involvement in the present case.

The case, Dr. Schuster believes, is most easily ascribed to a toxemia of unknown origin for which there is no evidence of bacterial infection.

The condition of the liver and kidney is obviously abnormal, but sheds no light on the original cause. The liver is in a state of disorder that may quite possibly be due to toxemia, but this microscopical picture is commonly associated with such extreme debility and diarrhea as was observed in this case. The kidneys show definite signs of a recent glomerulitis and tubular degeneration, but there are no collections of inflammatory cells and the interstitial tissue is unaltered. The histology of these two organs confirms the proposition of a toxemia, but does not help towards an explanation of the nature or sequence of events.

Goitre in Children.—A. S. Jackson (*Archives of Pediatrics,* June, 1925) states that iodine deficiency is generally accepted as the cause of simple or colloid goitre in children. Excessive physical and mental fatigue is also a factor in the etiology of simple goitre, as it adds an extra load to the thyroid gland. Goitre in children may be classified under three headings: colloid, adenomatous, and exophthalmic. The adenomatous type is subdivided into three types: nontoxic, toxic, and iodine hyperthyroidism. Colloid and adenomatous goitres are the result of a compensatory hypertrophy on the part of the thyroid gland, to supply the deficiency of thyroxin. Although colloid goitres apparently cause no symptoms, the disturbance in the thyroid gland may result in a general impairment of the vitality of the body. Adenomatous goitres rarely become toxic in children unless by the injudicious use of iodine. Exophthalmic goitre rarely occurs in children under ten years of age but is observed more frequently in persons between twenty and forty years of age. In nine cases of exophthalmic goitre in children observed by the author, all but one of which received treatment with iodine, the patients were successfully operated on. All children living in the goitre area should receive prophylactic treatment with iodine, which should be started at the age of ten. If small adenomas are present, treatment may be continued until the age of twenty-one, provided small doses are given with care.

Duodenal Contents of Infants in Health, and During and Following Diarrhea.—Wilburt C. Davidson (*American Journal of Diseases of Children,* June, 1925) presents data which suggest that in digestive disturbances in infants, especially in diarrhea and to a lesser extent in bacillary dysentery, the activity of the duodenal amylase and trypsin is decreased, and the hydrogen ion concentration of the duodenal contents and the numbers of colon bacilli in the duodenum are increased. While no definite conclusions can be drawn until more observations are collected, at present it would seem plausible to suppose that five factors may be responsible for the production of diarrhea in infants: 1, a primary cause which is at present undetermined but which may be different in individual cases, namely, external heat, fever, infections and overfeeding with an improper diet; 2, a reduction in the activity of the duodenal enzymes and secretions as a result of the primary insult; 3, an accumulation of undigested and unabsorbed food material in the duodenum as a consequence of the reduction in enzymic activity; 4, the invasion of this food material by organisms of the colon group from the cecum aud large intestine, and 5, the fermentation of this food material by these organisms and the formation of irritating end products which accelerate peristalsis and produce diarrhea.

Origin and Treatment of Congenital Stridor.—Karl Benjamin (*Monatsschrift für Kinderheilkunde,* June-July, 1925) states that the common inspiratory stridor of infancy (congenital stridor) can be temporarily relieved by drawing forward the lower jaw, by elevating the floor of the mouth, and by depressing the tip of the tongue. It also disappears on crying, when the expiratory position of the larynx during crying persists into the inspiratory crying pause. All of these procedures elevate the root of the tongue and straighten out the epiglottis. The noise of the stridor originates in the vibration of the free borders of the laryngeal rim, which is not stretched out in the infant as it is in the adult, but as a result of the high position of the larynx and of the relative large size of the tongue, is cramped loosely over the glottis and is therefore more easily put in motion by the current of air. An abnormal shortness of the lower jaw appears to increase the physiological predisposition of the infant to epiglottic stridor. This condition disappears spontaneously with the growth of the lower jaw and the depression of the darynx. The enlargement of the thymus so frequently found in congenital stridor is not the cause of the stenosis, but may be considered to be its result, as every impediment to respiration produces a venous hyperemia of the thoracic organs.

Significance and Treatment of Fever in Infants.—In a vigorous article, J. La Bruce Ward (*Archives of Pediatrics,* October, 1925) upholds the remedial purpose and effect of fever in infants, a stand, as he says, taken by the father of medicine five centuries B. C. As far as experiments with animals are concerned it has been shown that when the animals are kept at high temperature their defense against infection and intoxication is more effective, thus enabling them to survive doses of bacteria to which the controls quickly succumbed. The author continues that in his opinion babies suffering from fever need treatment often quite diverse in method. When it is realized that the temperature curve is determined not only by the nature and severity of the disease but also by the age and nervous makeup of the infant, the absurdity of attempting to alter it merely because we think it should not exceed a certain arbitrary limit, is obvious. To speculate upon the cause of and reason for the characteristic temperature curves peculiar to certain diseases is interesting. Science may yet prove that the widely fluctuating and intermittent fever, characteristic of certain malarial fever for the metabolic processes producing such fever, is more inimical to the growth of the plasmodium than would be the slightly fluctuating, high temperature common in lobar pneumonia. Dr. Ward believes that no drugs should ever be used unless there is a clear indication of their necessity and adds in respect to medical antipyretics that they should be used only when the physician has satisfied himself that the patient will be benefited by a lower temperature and that hydrotherapy under expert medical direction has failed to accomplish this.

Two Cases of Occlusion of Bile Ducts in Infants.—W. M. Feldman (*British Journal of Children's Diseases,* July-September, 1925) presents two cases of occlusion of bile ducts in infants. The first was in a male twin whose twin sister was normal. The jaundice first appeared at the age of eight weeks. The serum tested gave an indirect van den Bergh reaction which is supposed to be characteristic of the hemolytic rather than the obstructive type of jaundice. The conclusion drawn was, first, that obliteration of the duct was due to some postnatal cause, probably septic absorption through the umbilicus and, second, that the van den Bergh reaction cannot be considered to be an infallible differentiating diagnostic test between the obstructive and the haemolytic types of jaundice. The author believes that all other cases in which jaundice is not evident at or within a couple of days after birth is of postnatal origin.

The second case was in a male infant ten weeks old suffering from jaundice which showed all the characteristics

of the obstructive type. The symptoms set in twelve days after birth. There was no history of umbilical sepsis and no toxic symptoms. Its weight at birth was eight pounds. There were no other cases of infantile jaundice in the family and the other children were healthy. There was no history of syphilis. The infant appeared well nourished, although its weight at the time was only eight pounds two ounces; the skin and conjunctivæ were deep yellow, and the liver edge was three fingerbreadths below the costal margin. Biochemical tests gave the following results: First, fragility of red cells normal; second, Wassermann reaction negative; third, van den Bergh's test gave both the direct and the indirect reaction which is not inconsistent with the modern theory of jaundice. Upon operating, the gallbladder and all the bile ducts were found to be stenosed so that nothing useful could be accomplished. The infant recovered from the operation but died nine days later. The author says that in his opinion if surgical methods were adopted in such cases as soon as the jaundice manifests itself that they might be attended with success.

ENDOCRINOLOGY

The Problem of Senescence and the Doctrine of the Glands of Internal Secretion.—E. Gley, after recounting (*Revue Francaise d'Endocrinologie,* March-April, 1925) the work of Brown-Séquard, Steinach, Ancel and Bouin, Lichtenstern, Benjamin, Sand, Lespinasse, Voronoff, Thorek, and Parhon and Kahane, says these several experiences show that new testicular hormone applied to exhausted tissues causes a reawakening of their organic activity. Enfeebled genital function has been aroused by all these workers, or even restored when wholly absent, but there is no evidence that life has been prolonged. Are old age and death a necessity or a contingency? There are forms of life, vegetable, and protozoan, and even higher types, which appear never to become senile. They alone possess the astonishing property of preserving unaltered the faculty of growth. In creatures whose growth ceases decline is inevitable. It may be then that the problem of senility is nothing but a question of growth. But, besides loss of the faculty of growth, the being who grows old presents irreversible alterations in the colloidal state of the cells of different tissues. Thus the age of their secretion determines the age of the sex glands, instead of being determined by it. Whatever the procedure essaying to activate the testicles, restitution on the one hand can be no more than temporary, and on the other hand can alter nothing regarding these irreversible organic modifications, can only produce functional changes.

Organotherapy, Present Achievements and Future Prospects.—H. Lisser says (*Endocrinology,* January-February, 1925) that there are certainly two and possible three endocrine extracts which are standardized, strongly potent, uniformly reliable, and specific, and which, when properly administered under appropriate circumstances will yield consistent and convincing results. These are thyroid extract or thyroxin, as used in myxedema and hypothyroidism; insulin, as used in diabetes mellitus; and possibly pituitrin, respecting which the doubt hinges upon the pituitary origin of diabetes insipidus. Adrenalin, although standardized, potent, and even synthesized, "has not been consistently or convincingly effective in the relief of the only adrenal deficiency syndrome that we are sure of, namely, Addison's disease."

A second group includes those endocrine substances which have produced remarkable improvement in specific deficiency syndromes, where the favorable response to the gland administered seems incontrovertible, but where results are not wholly dependable or consistent. These comprise the pituitary extracts, and ovarian and testicular substance by transplantation.

In a third class stand other endocrine extracts where occasional benefit may have been obtained from their employment. In this group belong parathyroid, pineal, adrenal, thymus, prostate, mammary and placental extracts.

The author deprecates pluriglandular therapy. One of the best methods, he says, of judging the potency of an endocrine extract is to study the effects of overdosing. An excess of thyroid extract produces unmistakable signs of thyrotoxicosis. One dare not be careless in overdosing with insulin. Excessive amounts of adrenalin and pituitrin produce annoying symptoms. We may well ask what similar alarming or dangerous symptoms are produced by very large doses of whole pituitary, ovarian, testicular, parathyroid, pineal, adrenal cortex or thymus extract.

Corpus Luteum Extract as a Hemostatic Agent.—K. Prerovsky (*Bratislavské Lekárske Listy,* February, 1925) says that extract of the whole ovary has no effect on blood coagulation. Aqueous extract of corpus luteum, on the contrary, possesses a very pronounced styptic property when adiministered subcutaneously or intravenously. Orally it is without effect. The maximum hypercoagulability is reached from the third to the fifth day after instituting daily administration of two cubic centimetres of the extract. But the corpus luteum begins to take effect half an hour after the injection, and the hypercoagulability so induced lasts from ten to eighteen hours and only disappears completely on the sixth or eighth day. Repeated doses tend to diminish the styptic effect. On the whole the extract acts more energetically on coagulation of capillary blood than on that of venous blood.

The mechanism by which the corpus luteum acts is not that of a direct influence nor that of protein action or the ordinary effect of a cytozyme. Probably it takes place by the intervention of the liver, causing a profound alteration in the composition of the tissue fluids, especially as regards their cytozymoid content. To stabilize the blood of a subject in whom a massive injection of corpus luteum has been made a much larger dose of antithrombin is necessary than in controls.

Genital Organotherapy in Basedow's Disease.—This special form of organotherapy, advocated by Goglia (*Revue Française d'Endocrinologie,* March-April, 1925), is based on the functional antagonism between the thyroid and the genital glands. The therapeutic results are favorable when characteristic signs are present of ovarian insufficiency, and even when these are absent. There is no contraindication to this method of therapy.

The Parathyroid Glands and Their Iodine Content.—A. M. Hjort, O. M. Gruhzit, and A. G. Flieger (*Journal of Laboratory and Clinical Medicine,* September, 1925) analyzed specimens of desiccated parathyroid, pituitary, thymus, and ovary from the ox, calf and hog, and found the iodine content of the parathyroids to be no greater than that of the other glands. The iodine found in these glands probably represents the normal distribution of that substance throughout the body tissues. Parathyroid preparations made from the external bovine glands were not contaminated with thyroid tissue.

Shock Doses of Bacillus Coli Vaccine in Exophthalmic Goitre.—Arthur C. Wilson (*British Medical Journal,* March 7, 1925) reports his results with shock doses of Bacillus coli vaccine in eighteen cases of exophthalmic goitre. The dose was five hundred million bacilli. No case required more than six injections, which were given every seven days. Rest in bed was not found necessary, except in severe cases. Every patient had the classical symptoms and the benefit from the vaccines persisted long after the cessation of the injections. In nearly every instance the Bacillus coli was found in the urine. Every case resulted in a cure. The vaccine treatment of simple goitre proved to be less successful in the hands of the author.

Studies of the Thyroid Gland.—F. S. Hammett (*Psychiatrisch-Neurologische Wochenschrift,* June 13, 1925) made a systematic intensive study of the significance of the internal secretions in relation to age, examining carefully the organs and tissues removed from several hundred white rats in seven series, which had undergone deprivation of the thyroid and parathyroid glands at the conclusion of puberty and at six succeeding periods twenty-five days apart and were sacrificed five months later. Interesting conclusions are drawn from the completed examination of the seventy-five day and of the hundred day series. The younger the animals, the less influence has thyroidectomy in checking growth. Absence of glandular action has a more preceptible influence over growth in general in the case of female than of males. A very demonstrable effect on the rats operated on at one hundred days is a strong tendency to dehydration, demonstrating that the thyroid gland takes part, at any rate in the growing organism, in fluid exchange and must be taken into account in dealing with edema. Growth of the brain was found to be restricted more by removal of the thyroid than growth of the spinal cord. In males alone does pituitary enlargement take place as a result of thyroidectomy, while in females retardation of pituitary growth or absence of any change is observed. The thymus is exceedingly sensitive to thyroidectomy. Numerous observations were made to ascer-

tain the effect of lack of thyroid secretion on reproduction. It was established that conception takes place and young are brought forth when completely thyroidectomized females are mated with completely thyroidectomized males. No apparent impairment of the gonadal internal secretions could be detected. Still certain phases of reproduction, such as the formation, ripening, and expression of the sex elements, were unquestionably interfered with, as well as the events following fecundation. This is seen in the increased sterility, the age above normal of attaining puberty, the high birth mortality, the high mortality during and after weaning, the small number of young in a litter, and in the fact that the young rats do not thrive during the nursing period as with a normal mother.

Treatment of the Consequences of Arrested Menstruation by Irradiating the Pituitary and the Thyroid.—J. Borak (Vienna) remarks on ovarian hypofunction (*Münchener medizinische Wochenschrift,* June 27, 1924) as a cause of hypofunction of the pituitary and the thyroid. All the disturbances dependent on cessation of ovarian function may be very rapidly and very effectively ameliorated by irradiating the pituitary and thyroid glands, especially the former. Radiotherapy acts by inhibiting the endocrine cells.

Influence of the Autonomic Nervous System on the Function of the Thyroid Gland.—J. Hamilton Crawford and J. N. J. Hartley (*Journal of Experimental Medicine,* August, 1925) investigated the influence on the histology of the thyroid gland of section or stimulation, either singly or combined, of the various nerves which pass to the thyroid gland. The microscopic picture of the thyroid in normal animals was the same in the two lobes in the same animal, and therefore one lobe could be used for the experiment and one for the control. No histological difference was noted in the structure of the thyroid gland either from cutting off the nerve supply or from nerve stimulation.

Clinical Significance of the Congenital Absence of the Upper Lateral Incisor Teeth.—H. Wheelon (*Endocrinology,* January-February, 1925) presents four cases and gives a review of the literature. Heredity is a strong feature, there being altogether twenty-nine known instances among immediate relatives of these four patients where absence or serious deformity of lateral incisor teeth occurred. Lucas in 1888 published several cases of patients with such anomalies who had children with congenital deformities, in most cases harelip and cleft palate. More recently Kaplan has connected abnormality of upper lateral incisors with gonadal disturbances *teratologically ab ova,* and Timme with pluriglandular disturbances. The author canvasses at some length the evidence presented by his cases in support of each one of these three suppositions, and finds no conclusion justified at present.

THERAPY

New Method of Treating Varicose Veins with Injections of Fifty Per Cent Glucose Solutions.—F. Remenovsky and R. Kantor (*Wiener klinische Wochenschrift,* May 14, 1925) report very good results with intravenous injections of fifty per cent. glucose solution into the varicose veins. The following technic must be closely followed: The use of the thinnest needle possible to avoid escape of the fluid from the vein after the removal of the needle; puncture of the congested vein; after the release of the stasis, the massaging of the blood from the congested area toward the heart; compression of the vein for a distance of a few centimetres above the congested area with the index finger and prevention of the approach of the blood from below by compression and stretching of the skin below the site of puncture with the thumb; slow injection of the solution with the most careful avoidance of paravenous injection (pain and heal); withdrawal of the needle with continued compression above and at the site of the puncture for two to three minutes.

It was found that the sixty per cent. glucose solution was especially well suited to bring about occlusion of the vein by a vascular alteration and inflammatory closure. If properly followed the procedure is absolutely painless, and a rapid thrombosis is avoided. The inflammatory reaction sets in more rapidly than with the use of other solutions. The patient is not kept from work and is not otherwise inconvenienced. The usual dose is five c.c., but ten c.c. may be given, or less if the reaction is too marked. The general circulation of the limb is also markedly improved.

Rectal Digitalis Therapy.—S. G. Zondek (*Klinische Wochenscrift,* July 9, 19925) draws the following conclusions from his experiences with rectal digitalis therapy:

There need no longer be any doubt as to the efficacy of this form of digitalis therapy, as the drug is well absorbed from the rectum, and it is no less effective than when given by mouth. It is even distinctly more effective in static conditions in the portal vein circulation. The subcutaneous and intramuscular injections of digitalis can thus be eliminated. Whenever a rapid effect is desired, the intravenous use of digitalis, however, is the best. A combined intravenous and rectal use of digitalis may also be indicated, as in the early days of a course of digitalis, in which case strophanthin may be given intravenously and digitalis in suppositories. The rectal therapy should also be combined with diuretics. Irritation of the rectum from digitalis suppositories has been observed only exceptionally, when the symptoms were only of a transient nature.

Treatment of General Paralysis and Tabes by Tryparsamide.—W. S. Dawson (*Lancet,* May 23, 1925) states that the spirocheticidal action of tryparsamide is relatively feeble, but it has a marked tonic effect; it promotes recovery from toxic injury and induces the healing of syphilitic lesions without increasing the liability to a generalized spread of the spirochete. At the same time it has very little local or general irritant action upon the tissues, and cumulative effects are infrequent. Moreover, experiments indicate that it has a greater power of penetrating into the cerebrospinal fluid than other arsenical preparations. Its sole disadvantage is a tendency to cause amblyopia which is usually transitory, but may rarely be permanent.

In none of the author's series of twenty cases was there produced any remarkable result such as might not possibly have been obtained by the administration of other arsenic compounds. Several cases of paresis appear to have had their downward course arrested, while others have improved to a lesser extent. Whether tryparsamide is really more potent than other arsenicals is not proved in the author's series of cases, but the drug is certainly worth further trial. It is easy to administer and does not appear to be toxic in the doses used—eight weekly doses of two grams, dissolved in five to ten c.c. of distilled water intravenously or intramuscularly. The latter appears to be preferable as it is less quickly eliminated from the system. There was no general reaction except in one case in which a rigor occurred several hours after one injection

Rectal Injection of Ether in Whooping Cough.—As a result of his studies C. Elgood (*British Medical Journal,* May 23, 1925) found that drugs still hold their place in the treatment of whooping cough. Of these belladonna seems to be the most useful. Ether will check the disease completely in twenty-five per cent., fail completely in twenty-five per cent., and be followed by considerable improvement in fifty per cent., of the cases. Ether neither causes nor prevents complicating bronchitis; bronchitis already present is not a contraindication to its use. The method of administration seems to be of no importance provided the dose is large enough.

Treatment of Inflammations with Röntgen Rays.—H. Cramer and H. Kalkbrenner (*Klinische Wochenschrift,* May 21, 1925) report their experience with the use of röntgen rays in chronic and acute inflammation as follows:

1. An inflammatory process can undoubtedly be favorably influenced by röntgen rays with a superficial dose of twenty per cent. of the skin unit dose.
2. Acute inflammations can be influenced more readily than the chronic inflammations; occasionally the latter may even be refractory to this form of therapy.
3. The most favorable time for the induction of röntgenotherapy appears to be that of the beginning of the inflammation, and the time of the height of the inflammation seems to be less favorable.
4. The favorable effect is seen principally in the relief from pain, in the improvement of the general condition, and in the shorter duration of the inflammation (accelerated course of symptoms).
5. The surgical treatment of inflammations is considerably aided by a combination with a course of röntgen irradiation.
6. The authors explain the rationale of röntgenotherapy by the stimulation of a physiological protective apparatus to increased function—a complex process, the individual steps of which are not as yet certain.

Medicolegal Notes.

INTERNAL CURATIVE MEDICINE DEFINED

In a prosecution of an osteopath for practising medicine without a license in violation of Acts 39th Gen. Assem. c. 77, §15, which prohibits osteopathic physicians "to prescribe or give internal curative medicine," the state conceded that the defendant was licensed to practice osteopathy and the defendant did not claim that he was licensed to practice medicine. The evidence established that the defendant wrote prescriptions for his patients and that the prescriptions were filled by a pharmacist. It was also shown that the drugs were administered internally to some of his patients. Some of the ingredients were creosote, tincture of cinchona compound, strychnine, solium salicylate, simple syrup, lime water, and liquid parapectic. The question of fact to be determined was whether the defendant prescribed and administered internal curative medicine. The Iowa Supreme Court held, State v. Gibson, 201 N. W. 590, that the exclusion of expert testimony as to the technical meaning of the words "internal curative medicine" as used in the statute was not error, these words not imparting a technical meaning; and the trial court's definition of the words in its charge to the jury as "a medicine that is taken internally for the purpose of curing or tending to cure any disease" was held to be in harmony with the statute.

JAMAICA GINGER NOT INTOXICATING LIQUOR IN MISSISSIPPI

The Mississippi Supreme Court holds, Davison v. Town of Newton, 102 So. 161, that Jamaica ginger, or essence of ginger, put up in accordance with the United States Pharmacopœia, and having a recognized medical value and use, is not such an "intoxicating liquor" as is prohibited from being possessed by Miss. Laws, 1918, c. 189, although, if drunk to excess, it may produce intoxication, and although, if sold as a beverage, the seller may be convicted of selling intoxicating liquors. Section 2 of the act does not prohibit the possession of proprietary remedies or patent medicines intended for use as such, although they contain alcohol in sufficient quantities to produce intoxication if drunk to excess, if the percentage of alcohol be indicated thereon as required by law; it being lawful to sell such preparations as medicines, their possession cannot be unlawful per se. Consequently tincture of ginger or Jamaica ginger, prepared in accordance with the pharmacopœia, does not constitute intoxicating liquor per se. If a person sells such preparations as beverages, or with knowledge that they are to be used as beverages, it is held that he may be prosecuted under the Mississippi laws for selling them, but mere possession of them does not constitute an offense.

CHIROPRACTICS REQUIRE CERTIFICATE FROM STATE BOARD OF MEDICAL EXAMINERS IN LOUISIANA

The Louisiana Supreme Court holds, Louisiana State Board of Medical Examiners v. Cronk, 102 So. 415, that as under section 13 of the Medical Act, No. 56 of 1914, the mere direction or application of physical force for the treating, curing, or relieving any disease or ailment without having obtained a certificate from the state board, as required by section 15, is made an offense, the adjustment of vertebræ with the hands by a chiropractic without obtaining such a certificate is a violation of section 15, may be enjoined. Neither a state nor a municipal license entitles a licensee to pursue his business in violation of the criminal laws of the state, or in violation of the ordinances of a city. The state, in the legitimate exercise of its police power for the protection of the public health, is authorized to make provisions deemed necessary for that purpose, and to determine what is, or shall constitute, the practice of medicine. Such provisions cannot be construed as an illegal interference with the constitutional right of every citizen to earn a living.

CHIROPRACTOR'S TREATMENT OF RHEUMATISM REQUIRES CERTIFICATE FROM STATE BOARD IN ALABAMA

Alabama Code 1923, Sec. 5191, makes it unlawful for any person to treat or offer to treat, by any system of treatment whatever, diseases of human beings in the state without having obtained a certificate of qualification from the state board of medical examiners. The Alabama Supreme Court holds, Robinson v. State, 102 So. 693, that a chiropractor's treatment of rheumatism is such a treatment of disease requiring such a certificate; and in *quo warranto* proceedings to exclude the defendant from practising the profession of treating diseases of human beings without a license in violation of the statute, when the state proves acts done by him which he is prohibited by statute from doing unless he has authority by certificate or license, the defendant has then the burden of showing the authority by proper certificate or license, the proof of these facts being peculiarly within his knowledge.

EMPLOYERS OF INJURED WORKMAN HELD NOT LIABLE TO SUBSTITUTE EMPLOYED BY THEIR PHYSICIAN

The Alabama Supreme Court holds, Johnson v. Roberts, 103 So. 563, that generally, a physician employed to treat an injured employee has no authority to employ another to assist him at the employer's expense. Dr. Rosamond, a physician and surgeon who performed operations, was employed by a firm to take care of an injured workman and "to do everything necessary," and "not to leave a stone unturned in attempting to save his foot." Dr. Rosamond employed the plaintiff, also a surgeon and physician, to perform an operation on the foot and to treat it. The plaintiff presented to the defendant firm a bill for his services, which they refused to pay, and he sued the firm. The Alabama Supreme Court reversed a judgment for plaintiff for the reason that the defendants' instructions to Dr. Rosamond gave him no express or implied authority to employ the plaintiff to assist him, nor to turn the case over to plaintiff and let him perform the operation and services at the expense of the defendants.

"Dr. Rosamond," the court said, "in this employment to treat Taylor, was an independent contractor, without any control or suggestion by the defendants as to what he should do for Taylor, or how he should treat him. He was free to treat the case as he should choose, but he was not the agent of the defendants in so doing and he was not the agent of the defendants by this employment and contract.

"The plaintiff had no contract, express or implied, with defendants to perform the services for Taylor, and they did not request him to do so. He was employed by Dr. Rosamond, without authority, express or implied, from the defendants to render these services for Taylor, and the defendants are not liable for his compensation."

MEDICAL TESTIMONY TO IDENTIFY ACCUSED

Where the matter under inquiry in a criminal proceeding was the identification of the accused as to one who had committed a theft, the Louisiana Supreme Court held, State v. Butler, 103 So. 332, that the physical examination or facial observation of the accused by a doctor on the stand to determine whether accused's face was pox-marked was not improper or prejudicial to the accused, and a question as to whether the accused had pockmarks was not leading or suggestive of the answer.

A National Review of Medicine and Surgery, Established 1843

VOL. CXXIII, No. 3 NEW YORK, WEDNESDAY, FEBRUARY 3, 1926 WHOLE No. 2322

The Case Against Indiscriminate Surgery for Peptic Ulcer*

WALTER A. BASTEDO, M.D.
New York

In the treatment of gastric and duodenal ulcers there is a certain rôle to be performed by surgery; but it is my object to call to your attention some of the drawbacks and limitations of surgery, and to advocate medical treatment for all ulcers unless these have a surgical complication. The more noteworthy surgical complications of ulcer are: perforations, acute or chronic; hemorrhages, if large and recurrent; and obstructions such as pyloric stenosis and hourglass constriction. In addition we have the cases that fail to heal under medical treatment, for if medical treatment fails what is left but surgery? Yet in these cases we must be careful not to buoy our patients with too great an expectancy of a permanent return to a symptomless stomach and normal digestion.

MEDICAL TREATMENT

A word about medical treatment. Last year I treated successfully, so far as we can judge at this time, three cases of ulcer which had been treated medically with failure by three internists of the highest repute in three of our great cities, two being professors of medicine and one an assistant professor of medicine. In each case the treatment had lasted not over four weeks and the patient was let go from the doctor's care with the impression that his ulcer was healed. In each case the injunctions about diet and the subsequent care of the stomach had been perfunctory and totally inadequate, and in one case the doctor had permitted "a cocktail now and again." This is not the medical treatment of ulcer, it is maltreatment. But it is just this kind of maltreatment by supposedly good medical men that has justified the surgeon in taking into his domain many cases that could with less risk be cured by adequate medical measures. To evaluate medical treatment by examples of this kind would be as absurd as to appraise surgical treatment on the work of the average small town surgeon, whereas our surgical statistics are issued by eminent abdominal surgeons whose numerous cases would indicate the great extent of their experience and their exceptional opportunities for the development of technical skill in their operations. When therefore we speak of a course of medical treatment, we should mean adequate treatment by someone competent to give it and extending for a period of not less than a year. Very soon if the case is really surgical it will prove itself so.

GASTROENTEROSTOMY

In a paper read before this academy in May, 1924, I expressed the opinion that gastroenterostomy as the treatment for peptic ulcer starts under a serious handicap since it has an operative mortality of three to six per cent. and in those who do not die from the operation it is followed by two to five per cent. of marginal or jejunal ulcers. Since then Berg and Lewisohn have raised these figures considerably, for not only has Berg had thirty per cent. of secondary ulcers following gastroenterostomy and Lewisohn thirty-three per cent., but they call attention to the fact that the operative mortality of gastroenterostomy must be enlarged to include the high percentage of deaths which follow the secondary operations that are necessitated by the untoward sequelæ of the primary operation.

In addition to these deaths and new ulcers developing as the result of operation gastroenterostomy must meet a number of other charges, namely, 1, failure to cure; 2, failure to prevent hemorrhage and perforation; 3, failure to present the development of a new ordinary peptic ulcer—strange, is it not, that the condition established operatively for the express purpose of curing an ulcer failed to prevent the development of a new ulcer; 4, resulting gastrocolic fistulæ; 5, intraabdominal hernias (such as are produced by the slipping of the small intestine through the opening in the transverse mesocolon or behind the anastomotic loop of the jejunum); 6, external hernias through the wound in the abdominal wall, and 7, symptom producing intraabdominal adhesions.

Furthermore, in a number of cases when the surgeon opens the abdomen with the intention of doing an operation for ulcer, he finds no ulcer; in which event he removes the appendix and sews the patient up again, or still worse, performs a gastroenterostomy when there is no indication for it. Under wrong diagnosis of ulcer who would not prefer a medical "cure"? These cases should be added to the charges against surgery for ulcer, but occasionally the charge is offset when the surgeon finds some other lesion such as a cholecystitis, which justifies his operation in that particular case.

OTHER FORMS OF SURGERY

Besides gastroenterostomy there are other forms of surgery somewhat in vogue, and all have a higher operative mortality than gastroenterostomy. Berg's operative mortality in 150 cases of subtotal gastrectomy has been about nine per cent.

RISKS INCURRED IN MEDICAL TREATMENT

What do we risk by giving our patients medical treatment? We risk renewed or continued ulcer symptoms, extension of the ulcer with involvement of neighboring structures, hemorrhage, perforation and change to cancer.

Does surgery remove these menaces? Omitting consideration of the comparatively new and not as yet much practised subtotal gastrectomy, we shall discuss other forms of surgery. Does surgery remove these menaces?

1. *Renewed or continued ulcer symptoms.*—Of renewed or continued ulcer symptoms surgical literature furnishes a large number of records. These have to deal for the most part with three conditions, viz., failure of the original ulcer to heal, the development of a new ordinary peptic ulcer, and the development of an anastomotic or jejunal ulcer. There are many cases on record of the development of new ulcers similar to the original one and even perforation and hemorrhage while a gastroenterostomy stoma was in good working order; but more frequent are the marginal or gastrojejunal ulcers which are a direct sequence of the primary operation. In some of these secondary ulcers there is recurrence and a second or third operation is necessitated. Deaver remarked: "I have one patient upon whom I have operated three times for marginal ulcer and who now, I feel quite sure, has a fourth," and Lewisohn reports a case that had a fourth operation in six years from the same cause. These marginal and jejunal ulcers occur frequently, but published statistics have a wide range of difference, varying from the one to three per cent. of the Mayo Clinic, Horsley's four per cent., and Roeder's not over five per cent. to the thirty per cent. of Berg and the thirty-three per cent. of Lewisohn. In reporting the cases from Eiselberg's clinic, Denk stated that the number of these ulcers had increased from 12 in 1903 to 309 in 1920. According to Rankin and C. H. Mayo, ten per cent. of them go on to fistula formation with the colon, a very serious complication; Bolton and Trotter also mention ten per cent., Lion and Moreau twelve per cent., and Loewy reports 76 in 400 jejunal ulcers (nineteen per cent.). In sixty-three operations for such colon fistulas Loewy reports twenty-seven per cent. of deaths and 11.1 per cent. of recurrences. After a stomach operation the risk of a marginal ulcer is never absent, for though it usually occurs soon and may even occur while the patient is still in the hospital after the operation, Bland-Sutton reports the occurrence of one after seven years, I have had one after ten years, and Judd one as late as sixteen years after the operation.

Fortunately in most of the cases that pay the penalty of surgery with these secondary ulcers, which are frequently more productive of symptoms than the original ulcer, medical treatment is successful. But a number require a second or a third operation, and some even then require for cure long and persistent continuance of medical treatment, or are never cured.

2. *Extension of ulcer.*—The second risk is extension of the ulcer with involvement of neighboring structures. There is considerable evidence that surgery has with sufficient frequency failed to prevent this, but I shall take the time merely to quote Sir Berkeley Moynihan's statement that "In some of the reoperated cases the ulcer was still open and had usually perforated and become adherent to the liver."

3. *Hemorrhage.*—Those of us who have turned over a number of cases for surgery have been nonplussed to note a hemorrhage develop in some of them any time from a day or two to many weeks after the operation. Of gastroenterostomy cases Balfour of the Mayo Clinic reported hemorrhage in eight per cent. of those that had shown hemorrhage before the operation and in three per cent. of those that had had no previous hemorrhage. In Eggleston's series of forty-seven cases hemorrhage occurred in twelve per cent. of the patients some months or years after the operation, all having shown bleeding previous to the operation. Klein gathered reports of hemorrhage after operation as follows: Zweig in fourteen out of seventeen cases that had been operated upon because of the bleeding; von Petren in 7.4 per cent. of 203 gastroenterostomies; Rovsing in ten per cent.; Moynihan in a number, though the figures are not given. Kocher, Quénu and Eve each reported a fatal case.

4. *Perforation.*—From the literature Larrien gathered eighty-one cases of acute perforation following operation, and Douglas added twenty-nine. McKnight had two ulcer perforations at long intervals in the same patient though the gastroenterostomy stoma was functioning properly. Luckett tells me of a case in which seven months after gastroenterostomy for duodenal ulcer, he had to operate for a penetrating ulcer of the lesser curvature. The patient had been all the time on a plain bland diet and the gastroenterostomy stoma was working perfectly. Moynihan, Troell and von Haberer each report fatal cases. There are also fatal cases of perforated jejunal ulcers after gastroenterostomy (Lion, Barling).

5. *Change to cancer.*—In the duodenal ulcer the occurrence of cancerous change is so rare as to be negligible, therefore we shall confine our discussion to gastric cases. In these MacCarty of the Mayo Clinic reported his belief that cancer arises from ulcer in sixty-eight per cent. of the cases; and Wilson and McDowell of the same Clinic went so far as to say that "it is probable that gastric cancer rarely develops except at the site of a previous ulcer." On the other hand Kocher believes that cancer arises from gastric ulcer in only two per cent. of the cases, von Eiselberg in a possible four per cent. and Ewing, who made a thorough study of MacCarty's specimens, in three or four per cent. Wilensky and Thalheimer found cancer arising in only one of forty-eight specimens examined.

There are many statistics which show that it is comparatively uncommon to have an ulcer history in a cancer case. Nielsen in a study of 221 cases of positive ulcer observed from two and one half to nineteen years found none that became cancerous; while Friedenwald, in 1,000 cases of cancer of the stomach in which careful records had been kept,

found an ulcer history in 7.3 per cent. and some kind of preceding digestive symptoms in twenty-three per cent.

By means of a questionnaire to the members of the American Gastroenterological Association C. R. Jones made a summary of the clinical observations of these gastroenterologists. His findings might be stated briefly as follows: A very small percentage of gastric cancer cases have given a history of previous gastric ulcer, and a very small percentage of gastric ulcer cases have subsequently developed cancer. Indeed the majority of the members reporting think that there is very little relation between the two, many who have treated large numbers of ulcer cases being unable to report that cancer subsequently developed in any case, and the others a possible one to five per cent.

In stomach specimens received from the operating room with the diagnosis of simple chronic ulcer, M. J. Stewart found cancer in 11.5 per cent. (twelve out of ninety-eight cases), and Wilensky and Thalheimer found it in 18.7 per cent. The Mayo statistics are familiar. Ewing and many other pathologists believe that these cancerous ulcers of the stomach have practically always been cancer from the start and were never simple ulcers. Ewing suggests that these ulcers started as ordinary cancers and that the cancer tissue has for the most part digested off leaving an ulcer. Wilensky's case in which the ulcer showed no cancer whatever, but in which the adjoining lymph nodes were cancerous, supports this theory.

It would seem then that nearly all pathologists and practically all gastroenterologists hold the opinion that only a very small percentage of gastric cancers have their origin in simple ulcer, and that almost all ulcers that show cancerous development have been cancers from the beginning.

Balfour states that "during a seven year period at the Mayo Clinic cancer has been known to develop in thirty-three out of 799 cases operated upon for gastric ulcer. These known cases developed after every type of operation and no less frequently after partial gastrectomy than after gastroenterostomy with knife or cautery excision." Those in which the lesion was not removed and death occurred from cancer all conformed more or less to one type, namely, "large ulcer of posterior wall adherent to the pancreas too firmly and involving too much of the stomach to warrant risk of removal." Of these large ulcers, *the subsequent death rate following gastroenterostomy alone is twenty-five per cent.* Even after the ulcer was removed the percentage of ulcer patients dying of cancer after 296 cautery excisions with gastroenterostomy was 3.3 per cent., after 172 knife excisions with gastroenterostomy six per cent., and after 130 partial gastrectomies, three per cent. Later Balfour reports that in 1,280 operations for gastric ulcer in fifteen years 195 patients died following satisfactory recovery from the operation; and while only seventy-five of these were reported to have died of cancer, it is probable, in his opinion, that many of the others also died from the same cause.

Therefore, so far as cancer development is concerned, there is no especially preventive value in a simple gastroenterostomy, and statistics indicate that there is very little preventive value in any kind of surgery. If as indicated nearly all the cases that end with cancer are cancerous at the time of operation, though to the naked eye the lesions seem like simple ulcers, then any operation short of wide resection with removal of all lymph nodes, indeed quite as thorough and radical operation as is at present practised in cases of carcinoma of the breast, is essential. And this kind of operation is not done, though perhaps the operation of subtotal gastrectomy approaches it.

Such cases of course are not amenable to medical treatment. Yet there is scarcely a surgeon who has had a patient with cancer of the stomach alive ten years after the operation, and many have not had one alive after five years. And as Balfour has shown, even when the cancer is in its earliest stages so that not only is it not recognizable clinically but even fails to be recognized by the surgeon at the operation, many of the patients die later of cancer. Therefore, even if it were the custom to operate in all ulcer cases or supposed ulcer cases, and at the operation to remove the ulcer, which in a large percentage of the operative cases is not now done, it would still be probable that the chance of lessening the deaths from cancer in the possible five per cent. of cases which apparently develop from ulcer would be more than offset by the immediate or remote risks of such general surgery.

I do not mean to imply that I would not have a patient operated upon if I suspected the case to be cancer. On the contrary so far as any individual patient is concerned I should wish him or her to have what chance surgery offers. Surgery has helped many cancer cases for a time, particularly those with pyloric obstruction, and on rare occasions has restored the patient to health. But the claim advanced by surgeons that by the removal of all potential cancers surgery for all gastric ulcer cases would result in the saving of many lives is wholly fallacious, for such wholesale surgery would show a mortality that has never been reached by the deaths traceable to change of gastric ulcer to cancer.

Moreover, if the ulcer is healed, what greater reason is there to fear cancer development in later years if the healing has taken place under medical treatment than if it has occurred as the result of surgical measures? Therefore it is not a just claim that surgery gives a better chance than medical treatment of forestalling a future cancerous development.

There is one exception. The evidence would suggest that almost all ulcers which may give rise to cancer are the large ones of the posterior wall adherent to the pancreas, and for these we believe that radical surgery is the correct treatment; though it is just in these cases, which are difficult to handle, that the surgeon so often avoids radical treatment.

Thus the risks we run by giving our patients medical treatment seem at least in some cases to be present after surgery.

CAN MEDICAL TREATMENT CURE?

Eggleston reports that after the lapse of a period of at least three years, of 156 cases treated medically, seventy-two per cent. had had no return of symptoms, and of the twenty-eight per cent. showing recurrence the average duration of institutional treatment had been only three weeks. Einhorn reported ninety per cent. of cures in 315 cases. Lockwood's

patients, followed for over three years, gave fifty per cent. of cures.

Hewes in forty-nine hemorrhage cases without obstruction reported sixty-three per cent. of cures. Thirty-three of these patients followed the treatment for only one to two months and showed fifty-four per cent. of cures; while the other sixteen carried out the treatment faithfully with eighty per cent. of cures. Friedenwald in a comparison of different forms of medical treatment obtained sixty-six per cent. of cures with the Lenhartz method, seventy-two per cent. with the von Leube, and eighty-six per cent. with the Sippy method. Smithies has just published a report of seventy-seven per cent. of cures in 470 cases (128 gastric, thirty-six pyloroduodenal and 306 duodenal); but it is fair to say that these represented only sixty-one per cent. of his total ulcer cases, the remaining thirty-nine per cent. (302 cases) being considered surgical from the outset.

In a study of the specimens obtained by subtotal gastrectomy at Mt. Sinai Hospital, Crohn in April, 1925, reported that in thirty-four specimens of gastric ulcer none showed any predominant tendency toward healing, while in thirty-nine specimens of duodenal ulcer seven ulcers had healed or almost healed, in spite of the fact that most were cases in which a severe hemorrhage had occurred within a few weeks of the ulcer removal, and one patient had had repeated recurrences and pleaded for permanent relief by surgery. Later Crohn reported to the American Gastroenterological Association that two patients who came to the hospital because of hemorrhage from gastric ulcer and underwent medical treatment for only three weeks, were then operated upon by subtotal gastrectomy and the ulcers found entirely healed.

Ulcers may even heal spontaneously or as the result of simple medical measures, for at autopsy healed ulcers are not uncommon. Moreover, Stewart of London reported that among the healed ulcers found at autopsy *healed chronic ulcers were as frequently met with as healed acute ulcers.*

DOES SURGICAL TREATMENT CURE?

Among the surgical cases must be included practically all of the more severe ones, so surgical statistics start with a handicap. I shall not go deeply into these surgical statistics, for they are very numerous and in many reports show an almost unbelievably high percentage of cures. Yet Deaver's statement regarding gastric ulcer that "surgery allows ninety per cent. of patients to recover" might be compared with an analysis of Deaver's statistics of patients who were traced which shows only fifty-eight per cent. free from gastric symptoms and fourteen per cent. of deaths due to the original gastric lesion which had not healed or to complications resulting from the operation. And I might quote Bettmann and White's 140 cases of operation for gastric ulcer, with an operative mortality of ten per cent. and 57.9 per cent. apparently well at the end of a year; Crile's report that five years later only seventeen were well out of seventy patients operated upon for gastric ulcer; Denechau's that about twenty per cent. showed good results four to twelve years after operation; and Deaver's "Of the cases in which the ulcer was not excised and in which only a posterior gastroenterostomy was done (only) eighteen per cent. of the patients reported freedom from symptoms one to five years later." Peck reports an operative mortality of 8.8 per cent. in 228 cases of gastroenterostomy for duodenal ulcer.

In 273 traced cases of gastroenterostomy for duodenal and gastric ulcer Smithies found only 20.9 per cent. clinically free from gastric complaints, whereas Eggleston reported fifty-six per cent. of failures from surgery in forty-seven cases (of gastric and duodenal ulcer) seen later at the Battle Creek Sanitarium.

On the other hand we might compare with these the more recent Mayo statistics. Balfour, 1924, in 1,000 cases with chronic duodenal ulcer operated upon more than ten years previously, found that eighty-eight per cent. reported relief from the symptoms for which the operation was performed. And he stated that "At the present time there is no conclusive evidence that any operation is more useful than gastroenterostomy in chronic duodenal ulcer, except in carefully selected cases."

Of 1,228 operations for gastric ulcer at the Mayo Clinic in ten years, gastroenterostomy alone was done in 20.3 per cent., gastroenterostomy with excision in forty-seven per cent. Of 6,665 cases of chronic duodenal ulcer in nineteen years gastroenterostomy had been performed in 5,755, or 86.35 per cent., and in only 2.18 per cent. was the ulcer excised in addition. In the other 13.65 per cent. (920 cases) other operations had been performed, such as excision alone, pyloroplasty and gastroenterostomy and partial gastrectomy. Of duodenal ulcers Balfour says "The necessity for removal of the ulcer is comparatively infrequent," the advantage of excision being a doubtful one.

Of secondary operations Eusterman had already reported from the same clinic only 144 after 4,793 posterior gastroenterostomies and eighty-four after 1,609 other types of operation.

MEDICAL FAILURES VERSUS SURGICAL FAILURES

In the case that is *not* obviously surgical, barring the effects of some delay under favorable conditions, proper medical treatment as a rule does no harm, and if it is unsuccessful soon proves the need of more radical measures. The two greatest dangers in delay are perforation and hemorrhage, and under proper medical treatment it is quite rare to have either. Therefore without any great risk medical treatment can be given a thorough trial in every ulcer case that is not obviously surgical. If it should prove a failure, at least it permits the patient to be turned over to the surgeon in better condition for surgery than before the medical treatment. Deaver is one of the strongest advocates of operation in all cases of ulcer, yet even he admits that "as a preparation for operation medical treatment has its usefulness."

But what about the numerous unfortunate patients in whom after all the distresses of an operation, the ulcer has failed to heal, or in whom have intervened some of the serious sequelæ due solely to the operation? What about the three to six or ten per cent. who have died? What about the cases with gastrocolic fistula? One such patient of mine died after five subsequent operations and many years of misery. What about the patients such as Deaver's that is

to have the fifth operation for a fourth marginal ulcer, or Lewisohn's that had four operations in six years? The internist can refer his failures to the surgeon in good condition for the operation, but the surgical failure may return to the internist in a deplorable condition, and sometimes, do what we will, he remains a chronic digestive invalid for the rest of his life.

ALL SURGEONS DO NOT FAVOR SURGERY IN ALL ULCER CASES

Crile says, "In both types of ulcer medical treatment should be tried and tried faithfully with controlled alkalinizing and frequent feeding. If this fails the case is surgical." Ochsner states: "I believe that in seventy or possibly ninety per cent. of all duodenal and gastric ulcers, if treated properly before severe obstruction has resulted, the patient can be put in a position in which his stomach and duodenum will be a better machine than you can ever make surgically." Bevan is of the opinion that almost all ulcers in their early history should be treated medically, surgery being needed ultimately in about ten per cent.; while W. J. Mayo says, "The large majority of cases of peptic ulcer seen early are amenable to medical treatment," and of chronic ulcers only those which are intractable require operation.

DUODENAL VERSUS GASTRIC ULCERS

Undoubtedly in seriousness and amenability to treatment and for the most part symptomatology these form two distinct classes. Other things being equal the gastric ulcer is the more serious lesion, it is more prone to cause loss of weight, it more often causes acute pain or vomiting, its remissions are less likely to be prolonged, it is more likely to force itself upon the patient's attention, and as with medical treatment, so with surgical it shows poorer end-results and a higher mortality. Therefore, while we can subscribe to Balfour's 1924 opinion that in duodenal ulcer cases "a higher percentage of satisfactory end results could be obtained if surgical treatment were postponed until indications for it became more definite," yet in the gastric cases we would caution against undue delay in securing surgery if good results are not promptly obtained by the medical procedure.

THE CRITERION FOR SURGERY

Granting that there still exist great differences of opinion as to the efficacy of any medical or surgical treatment for ulcer, and acknowledging that a large percentage of peptic ulcer cases are curable by surgical means and a fair number are not curable by medical means; nevertheless, in the light of all the risks and drawbacks of which we have spoken, it is my opinion that we are not justified in employing surgery in the great number of cases that promise to do as well by medical treatment.

In deciding for or against surgery I adopt the surgical criterion that I follow in other cases, namely: that an operation is justifiable only where there is a decided percentage of chances in favor of the probability that the patient will be better with the operation than he could possibly be with any other form of treatment; or in other words, when the risks from the operation are distinctly less than the risks of going without the operation.

This excludes operation in all ordinary cases of ulcer. On the other hand it leads me to favor operation at the onset in the perforation or penetration cases, in the cases with repeated copious hemorrhage, in the obstructive cases such as those with persistent pyloric stenosis, hourglass constriction or obstructive adhesions, and in those who because of difficult circumstances or difficult temperament cannot or will not faithfully carry out a prolonged medical scheme. In all other cases I favor medical treatment, but I do not hesitate to recommend surgery if there is persistence for a few weeks of pain, nausea or sour stomach, if after adequate medical treatment there is recurrence with violence following a symptom free period, or if after a considerable length of time the patient proves unable, while living a normally occupied life, to ingest comfortably ordinary foods sufficient to maintain health and nutrition. Thus I figure that probably between fifty and seventy per cent. of all peptic ulcers will yield to a course of proper and prolonged medical treatment, and that only the others should be considered surgical.

This then is a brief presentation of the case against indiscriminate surgery for peptic ulcer.

33 East Sixty-Eighth Street, New York.

Habitual or Recurrent Dislocation of the Shoulder*

T. TURNER THOMAS, M.D.
Philadelphia

It is such a short time since reporting my experience in connection with these cases that my only excuse for writing on the subject so soon again is that you asked me to do so. It is impossible for me to know what interests you most, perhaps the operation through the axilla. For me the most urgent thing is to advance the idea of hyperabduction as the underlying causal force in the overwhelming majority of cases. It was responsible for the doing of the axillary operation which no one had done before. The only surgeon before me to suggest this mechanism of hyperabduction, so far as I know, was the late G. G. Davis, afterwards professor of orthopedic surgery at the University of Pennsylvania, and I got it from him. He did not tell in his paper where he got it but I know, from the cadaver. I saw him produce his first cadaver dislocation by hyperabduction in 1899 and many of them afterwards, and I have produced many of them myself and dissected many in various ways. On the cadaver this mechan-

*Read at the Annual Meeting of the Alumni of the Hospital for Ruptured and Crippled, in New York, November 23, 1925.

ism will produce a typical subcoracoid dislocation, such as we see commonly in life, every time unless the humerus breaks at the surgical neck and probably no other mechanism will produce it. Probably most falls on the hand end in abduction at the shoulder and sometimes in hyperabduction. We came to believe firmly in this as the mechanism for dislocations of the shoulder and to teach it and I came to believe in it as the great cause of most fractures and dislocations in the shoulder region, a dislocation being merely a fracture of the skeleton at a joint with displacement of the fragments.

What has this to do with recurrent dislocations of the shoulder joint? In the winter of 1906 and 1907 I was asked by a friend if operation would not provide a radical cure for this condition. He had a friend who contemplated marriage, was athletic and very ambitious, and whose plans in life were much interfered with by a recurrent dislocation of the shoulder. The knowledge of the average physician at that time is illustrated by the statement of the patient later to the effect that he had consulted as many as forty doctors, some of them surgeons, and had been advised by all without exception to let well enough alone, and one of them impressed him greatly by the information that if operated on he might end up with a stiff shoulder and shrivelled arm.

At this time I was compelled to admit that I had not seen, read, or heard of such an operation, but I did not hesitate to say that on the basis of my cadaver experience I believed I could cure the condition by operation. For me then the only pathology was a torn axillary portion of the joint capsule and the cure was to unite the margins of the tear. The only problem was to expose the tear sufficiently to permit a suture to be passed. The patient had recently purchased a leather shoulder brace, the chief purpose of which was to limit abduction, and he wished to try it out. A year later he returned, saying that I was the only one who had expressed confidence in his ability to cure the condition by operation, that I had confessed my lack of experience but that if I was willing to take the chance of operating he was. I operated in January, 1908, nearly eighteen years ago, and he has never had another dislocation since, has had normal function since a few months after the operation, and has done much athletic and other violent work with that shoulder. In this case only did I find evidence of a capsule tear in the upper margin of the torn capsule being found. In every case I found the capsule intact apparently but often very thin, and my conclusion has been that the gap between the divided margins became bridged across by a new cicatricial portion as the gap between the divided ends of the tendo achillis after operation for a talipes equinus becomes filled in by cicatricial tendon later.

A search of the literature showed that numerous theories for the etiology and pathology existed and a few patients had been operated on, the greater number by capsulorrhaphy for the contraction of a relaxed capsule, some of them by excision of the humeral head, one by arthrodesis. Ricard of France, who reported two cases (1) in which he reefed the capsule, was generally credited with originating the idea of contracting a relaxed capsule, but I found that Gerster of New York (2) had accomplished the same purpose in 1883 by excising an oval piece of capsule and suturing the cut margins of the capsule and the muscles together in three tiers. But most of these operations were done by an incision between the deltoid and pectoralis major muscles which was enlarged in various ways and always requires transverse division of the subscapularis tendon to expose the capsule.

Its chief objection is that it exposes the capsule too far external to the involved area to permit the most effective work on it. Hyperabduction at the shoulder thrusts the humeral head out of the socket by a leverage mechanism into the axilla behind the large axillary vessels and nerves, the circumflex nerve with its accompanying vessels crossing the prominence of the dislocated head. After repeated dislocations over a long period the torn capsule margins gaping apart over the protruding head become bridged across by a new portion of cicatricial capsule making the capsule abnormally long at the site of the dislocated head. To prevent the dislocations this relaxed portion of capsule must be contracted to within the normal length and strengthened, for which operation is necessary.

The acceptance and general performance of this operation has been retarded because the relaxed portion of capsule to be exposed is under and posterior to the large axillary vessels and nerves so that the surgeon not familiar with the anatomy prefers to make the exposure between the deltoid and pectoralis major muscles. With fair familiarity with the anatomy the axillary operation is the simplest, safest and most effective one, divides no muscles, practically no bloodvessels, and requires only a skin and fascial incision five or six inches long. Infection practically never occurs and in the one case in which it did occur the result was perfect, both as to motion and recurrence of the dislocation. There is probably less risk of infection than in a clean appendix or an inguinal hernia. The small wound, slight damage to the tissues and perfectly dependent drainage almost guarantee against infection.

RESULTS

There are two classes of patients especially prone to develop recurrent dislocations of the shoulder, athletes and epileptics, athletes because they will not immobilize and epileptics because they usually do not have the affected arm immobilized at the side of the body long enough to permit firm cicatrization of the torn capsule. The athletes belong to a much larger class of nonepileptics and in estimating the results of operation it is important to divide the cases into epileptics and nonepileptics because we should not expect as good results in the former as in the latter. I have included among my cases three of so-called snapping shoulder which is a very disabling condition and very poorly understood and this in turn probably accounts for the fact that it receives so little attention. I am now very strongly of the opinion that it is nothing more than a recurring subluxation of the shoulder joint in which the humeral head cannot leave the socket far enough to lock in the dislocated position when the arm comes down to the side, but goes out only a short distance to snap back on further movement. But I am not at all inclined to be dogmatic on the subject and am anxious for further light on it.

SNAPPING SHOULDER DISLOCATIONS

Recently I reported fifty-seven shoulders operated on, three being of the snapping shoulder variety. These latter are perhaps the most interesting because the least known and in many respects most troublesome because the snapping is associated with pain, weakness and interference with motion, and occurs many times a day, whereas the complete variety of dislocation may recur only at intervals of months. In my three cases two patients recovered completely after a capsulorrhaphy and one, the first, was only improved. This was the most interesting case because it raised the problem as to its cause. An orthopedic surgeon brought it to me because of its obscurity. We both agreed that its cause was intra-articular and in the nature of a subluxation, but neither could determine just where the head was jumping out of the socket which was most important because the curative contraction of the capsule should be done on that side. We finally decided to do this in the upper anterior portion and this resulted in only a partial cure. In the following two cases a contraction of the anteroinferior portion of the capsule as in the ordinary complete recurrent dislocation resulted in a complete cure. Recently, five and one half years after the first operation, this first patient submitted at the Northeastern Hospital before the Clinical Congress of Surgeons, to the operation performed in the two later cases, left the hospital six days after operation and has had uncomplicated healing.

DISLOCATIONS IN EPILEPTICS

Of the remaining fifty-four shoulders with complete dislocations, eighteen were in epileptics and thirty-six in nonepileptics. Of the eighteen in epileptics a capsulorrhaphy was done first in seventeen. In one powerful patient with frequent violent convulsions the condition was bilateral and in the first shoulder a capsulorrhaphy was done three times without success and later a high excision of the head of the humerus without further dislocations in that shoulder. The condition developing later in the other shoulder, resort was had at once to the excision without a preliminary capsulorrhaphy, and no more dislocations occurred in that shoulder. Between seventy and eighty per cent. motion developed in both shoulders. In another bilateral case a capsulorrhaphy was followed by no more dislocations in one shoulder, but in the other shoulder about the anterior half of the socket had been worn away by the very frequently repeated dislocations (many on one day as in a snapping shoulder) and the capsulorrhaphy while reducing the frequency of the dislocations did not stop them.

A Hildebrand operation for the reshaping of the glenoid cavity done fifteen and one half years ago has not been followed by a single dislocation. In two other epileptics failure of capsulorrhaphy was followed by a high excision and no more dislocations in the last case after three years. In the remaining thirteen epileptic shoulders capsulorrhaphy was sufficient for a complete and permanent cure. The above bone operations will always cure and it is very likely that the necessity for them can be materially reduced by a more prolonged immobilization of the arm at the side after the capsulorrhaphy.

DISLOCATIONS IN NONEPILEPTICS

No other operation than capsulorrhaphy was done in the nonepileptics and of the thirty-six, three were not heard from. Of the remaining thirty-three, in twenty-two, or sixty-six and two thirds per cent., a complete cure was obtained, i. e., no dislocations followed operation in periods ranging from seventeen and one half years to six months. In six cases only one dislocation followed operation which in the first case was done fifteen and one half years ago. Two dislocations followed operation in two cases, the operation in one case having been done sixteen years ago and in the other five and one half years ago. I saw this latter patient only once after his operation which was done June 2, 1920, and in reporting his case in 1921 he was considered a success because up to that time he had not had a dislocation since the operation. But a short time after that he reported that a dislocation had occurred and as I did not see him or have any control over him I felt that he would probably become a failure. In my recent report I was able to say that he had very recently written that he had but the one dislocation four years ago and had worked as a coal miner and played baseball regularly throwing the ball with the affected arm without any difficulty and that he considered the operation a remarkable success. Still more recently he was sent by the Veterans' Bureau to me on account of a new dislocation in the shoulder operated on, which occurred last June about a month after I had reported him a success and about five months ago. He still shows limitation of abduction in this shoulder of about twenty degrees which means that it is probably stronger than before this last dislocation.

A dislocation following operation in a nonepileptic is an advantage not a disadvantage in that particular case. It merely indicates that the operation did not furnish enough cicatricial strength at the site of the original dislocation and a new dislocation if properly treated by immobilization of the arm at the side afterwards will add the new cicatricial tissue just where it is most needed and probably another dislocation will not occur. If it does, the same immobilization afterwards will again add to the strength. As already stated I have had six cases in which one dislocation after operation has been sufficient and two in which two dislocations were necessary. Such a result could not be obtained without the performance of the operation which restored the conditions in a recurrent dislocation just after the first dislocation following operation to those immediately following the reduction of a first dislocation of a normal shoulder joint, i. e., in both there is a newly torn capsule which can be repaired only by the development of new cicatricial tissue between its torn margins. Proper immobilization of the arm following this will almost surely be followed by a strong capsule.

MOTION AFTER OPERATION

There is an intimate relationship between the return of motion after operation and the strength of the joint. The more slowly the return of motion after a capsulorrhaphy the stronger the joint. In a nonepileptic or an epileptic with sufficient mentality to work for it one need have no concern about the return of normal motion. Immediately after the removal of the bandages these patients begin with, at

least, abduction of the arm to a right angle and afterward one will be more concerned with inhibiting than advancing the return of motion.

As already stated in five shoulders in epileptics bone operations became necessary to stop the dislocations, in four a high excision of the humeral head and in one a reshaping of the glenoid cup. The latter operation according to its originator, Hildebrand (3) was followed by normal motion in the joint.

In my one case the result was brilliant so far as stopping the dislocations is concerned. The patient did not recover normal motion but very likely would have done so if he had mentality enough to desire and work for it. The high excision gave very good but probably cannot give normal motion. These operations should never be done in nonepileptics and probably need be done only very rarely in epileptics.

CONCLUSIONS

1. Hyperabduction of the arm by leverage action tears the joint capsule and thrusts the humeral head into the axilla. Repeated many times this leads to lengthening of the capsule here and loss of capsule resistance to hyperabduction.

2. The cure is to restore the capsule resistance by contracting the lengthened axillary portion. The axillary operation is easy, safe, does no damage to muscles, vessels or nerves, while the humeral head and overlying capsule are here almost subcutaneous.

3. No surgeon is justified in doing this operation before making himself familiar with the anatomy of the route, particularly with the relationship of the circumflex nerve to it. For his trouble in gaining this familiarity, he will be able to give a good prognosis for the operation.

Otitis Media Purulenta Acuta

LOUIS S. SMITH, M.D.
Brooklyn

The object of this article is to give the general practitioner some simple suggestions in the diagnosis and treatment of acute purulent middle ear disease before it has reached the stage of an active mastoiditis. It is extremely important that he should be familiar with the symptoms and realize the danger from neglect of proper treatment, not only to the function of hearing, but also to life itself.

SYMPTOMS AND SIGNS

The patient early experiences a sense of fullness of the affected side, together with a feeling of warmth in the head. Pain is usually not present at this stage, save a few twinges now and then in the affected ear. The temperature, however, usually is slightly above normal and soon starts to climb. This sense of fulness of the affected side and rise of temperature, should in all instances prompt the physician to examine the ear drum.

The physical changes in the drum membrane vary with the progress of the disease. Shortly after the initial symptoms we will find that the membrana tensa throughout the greater part of its extent is of a normal color except that the handle of the malleus is slightly congested. Shrapnell's membrane is also slightly injected. This appearance of the drum membrane itself should excite the suspicion of a catarrhal or a suppurative process in the vault, which later will extend downwards and involve the atrium. A few hours or a day later, we will find the upper half or the whole membrana tensa injected. The injection of Shrapnell's membrane is, however, much more intense and the infiltration is so pronounced as to indicate a suppurative process behind the membrane, namely, the vault. As the condition progresses, the part including, and immediately adjacent to, Shrapnell's membrane becomes markedly bulging, obliterating the drum landmarks. This clearly indicates the presence of pus in the tympanic vault. The entire drum membrane becomes an angry red and bulging, and the pain becomes so intense as to cause loss of sleep at night. In a few instances, pain is of a minor character. The temperature rises gradually, and may reach 103° to 105° even in adults. The patient looks ill and feels the same way. Perforation may occur with some relief of symptoms. As a rule, this perforation is too small to allow the escape of the suppurative products, and so the general signs and symptoms continue to progress. The posterior superior canal wall, i. e., that part immediately adjoining the drum membrane, becomes infiltrated and swollen, so that no line of demarcation is discernible between canal wall and membrane. This condition is commonly known as a "sagging of the posterosuperior canal wall," and it clearly indicates a severe suppurative process within the vault and a frequent coexisting inflammation of the mastoid cells. This condition should be clearly understood, for a study of the anatomy of the tympanic vault will readily show that pus collecting in the tympanic vault must find its way into the atrium. The atrium, therefore, is usually to some extent involved in a suppurative inflammation of the vault, and tenderness on pressure over the atrium is rarely absent in a very acute stage of suppurative purulent otitis media.

TREATMENT

General treatment.—The patient should be placed under the most favorable conditions for combating the local infection, namely, rest, regulation of diet and catharsis.

Absolute rest in bed is essential. This secures freedom from fatigue and excitement of daily routine. It protects the patient from sudden changes in per-

ipheral body temperature, which is so essential to aural disease where slight aggravation of a nasopharyngitis may cause rapid extension of the tympanic lesion. It should be remembered that the aural condition is always secondary to a nasopharyngeal inflammation.

During an acute stage of any suppurative lesion, the digestive function is easily disturbed. Keeping this in mind, the patient should be placed on a strictly liquid diet during the first twenty-four to forty-eight hours. As soon as the patient demands a more generous diet it should be changed to a light, easily digested solid diet. Avoid the use of red meats. Avoid a starvation diet in a patient with aural disease as it seems exceedingly senseless to deplete his strength and resistance powers by a prolonged starvation diet.

Regardless of the presence or absence of constipation or digestive disorder, some efficient laxative should be administered at the onset. The cleansing of the alimentary tract not only prevents digestive disturbances but also in some way exerts a favorable influence upon the tympanic lesion itself. Calomel in doses of one to three grains, according to the age of the patient, and followed in six to eight hours by a solution of magnesium sulphate, gives the best results. During the latter stages, teaspoon doses of rhubarb and soda mixture at regular intervals are very beneficial.

Local treatment.—The general practitioner should be able to manage the nonoperative treatment, i.e., the management of a case of acute middle ear inflammation without incision of the drum membrane. Incision is indicated only in a small number of cases as they are first seen by the otologist. When incision is necessary there should be no hesitation, and a specialist should be called to do the paracentesis.

When inspection of the drum head shows the lesion to be in an incipient stage, the abortive treatment should be tried. The patient is ordered to bed, and calomel, followed in six to eight hours by a solution of magnesium sulphate, is administered. Control of pain at this stage may not be necessary, but in hypersensitive patients the following prescription is of value, and in itself may favorably influence the lesion.

Codeine Ext. Belladonna	aa	gr i
Camphomonobrom Phenacetin	aa	gr v

M. Divide in chartulas No. x
Sig. One every four hours.

Avoid using opium for the relief of pain in acute otitis media as it may mask an important guide as to the progress of the lesion. In fact, it should never be prescribed. The application of dry heat is our chief reliance. This often does not wholly annul severe pain, but it often reduces very materially its intensity. The ordinary hot water bag should be filled half with water and then wrapped in one or more layers of flannel and the patient instructed to lie with the diseased ear in contact with it. Poultices over the ear are of no avail. Blistering and counterirritation over the mastoid should not be used, for their effect may subsequently mask mastoid signs. The use of hot or warm irrigations, which is a common practice, should not be employed, as they serve no purpose and in fact tend to aggravate the local condition. The instillation of phenol in glycerine five to ten per cent. at regular intervals also helps to allay pain and reduce the inflammation.

If at the end of twenty-four to forty-eight hours, these measures have seemed to control the symptoms, the abortive treatment should be continued. If the physical signs and symptoms continue to progress, the general practitioner should call upon the otologist, for the lesion has advanced to the stage of pus formation and retention and is now clearly a surgical condition. The local treatment in such cases is based upon two factors, as follows: 1, Providing free drainage from the tympanum by means of an incision of the drum membrane; and 2, keeping the external auditory canal as perfectly dry and free from pus as possible.

When inspection of the ear drum shows the membrana tensa to be bulging, there should be no delay in making a free incision through the posterior segment from the lower attachment to the middle of the posterior fold above, and if necessary through the fold. It is decidedly a wrong procedure to allow a bulging membrane to perforate of its own accord. A clean cut incision in the drum membrane immediately relieves the pressure, establishes drainage and the subsequent healing of the wound takes place with but little damage and no scar tissue. Nature's perforation is usually a small jagged hole, the borders of which are necrosed, and as healing takes place it is prone to result in scars, and considerable deposits of new connective tissue in the ear drum. Immediately following incision of the drum head, there is always a free escape of blood and pus into the external auditory canal. The patient experiences a marked sense of relief. Care must be exercised at this point to remove the clot of blood in the depths of the canal for if this is not done it partially or wholly defeats the purpose of the operation. Fifteen minutes after myringotomy the operator should remove this postoperative clot himself and not leave that duty to the nurse or patient. A sterile cotton applicator readily dislodges this clot.

It has been the common practice of physicians to employ routine irrigations of boric acid or sodium bicarbonate and the like in acute and chronic middle ear disease. This destructive practice should be discouraged. Otologists of reputation are gradually abandoning it. As Kerrison states in his textbook on *Diseases of the Ear:*

"I believe that every practical aurist will agree with me that the value of routine irrigations in acute middle ear disease depends much less upon the frequency than upon the thoroughness of the irrigations. The object in view is simply the complete removal of pus from the meatus. No matter how carefully the nurse may perform her duties, it will be found that the fountain syringe will in certain cases leave a residue of thickened pus at the bottom of the canal. Finally, there are certain cases in which one is forced to conclude that frequent irrigations tend to retard tympanic resolution. Such conclusion being reached, the irrigations should be discontinued or modified by combination with other measures."

It is clearly understood that although the object of irrigation is to clear the meatus of purulent dis-

charge, which empties into it from the tympanum, still in most cases the auditory canal frequently contains pus even after irrigation. This same purpose can be accomplished with far greater accuracy by a much simpler, saner and easier method than irrigation, and without the possibility of driving infection higher up into the tympanic vault and perhaps into the antrum. Patients get along better by not irrigating the ears.

The cleansing of the auditory canal can be accomplished by frequent swabbing with pledgets of sterile absorbent cotton wound about applicators or toothpicks at regular intervals, depending upon the rapidity and amount of secretion. As the secretion grows less the swabbing is done at longer intervals.

Besides treating the ear, attention should also be given to the existing nasopharyngeal condition to which the aural condition is secondary. A solution of argyrol ten per cent. should be instilled in each nostril at regular intervals and immediately followed by a one per cent camphor menthol in liquid albolene solution. A Dowling argyrol tampon should be inserted once or twice daily. The drum head should be frequently inspected to ascertain its patency, and partial or complete closure should warrant reincision. Very frequently, indeed, this procedure saves the patient the necessity of a mastoidectomy.

Some Views on the Problem of Anaphylaxis

SYDNEY PERN, M.R.C.S. Eng., L.R.C.P. Lond.
Melbourne, Australia

When we wish to investigate the functions of certain parts in such an extraordinary complex mechanism as the human body, we get a much better perspective by going back to the primitive organisms and watching the gradual unfolding of the tale through the higher forms of life, as by doing so we find in the lower organisms, one group of cells fulfilling the function of what later on has developed into a highly complex mechanism.

For the coordination of this vast machine it is necessary that every part of the body should know exactly what is taking place elsewhere and to be ready at any moment to assist for the general welfare of the whole. A certain amount of this information is responded to by conveying messages to our conscious nervous mechanism and voluntary response is given, but by far the larger part is outside of volition entirely, and is handled by our selfregulating mechanisms. It is this selfregulating mechanism with which I wish to deal.

Of a necessity such a mechanism must consist of two elements, one to increase the function of individual parts and the other to diminish function, as we know of no other powers possessed by cells of any of our organs. By this means a state of balance is maintained.

Arising from such a conception, the only things we have to do are to supply ourselves with food and warmth and certain other ingredients which are usually to be found in the food we eat. The rest of the management is taken out of our hands and conducted automatically. When we as intelligent beings really grasp this point it makes us marvel that so little is left to us as regards the welfare of our bodies. We are even prevented by pains and penalties from the possibility of neglecting to supply ourselves with food or exposing ourselves to the extremes of temperature.

How vast these automatic mechanisms are can well be left to our imagination, as the more we ponder over them the more numerous they seem to become. These function alike in health and sickness, but it is in sickness that we are now concerned with them.

In the makeup of our bodies Nature has been lavish in providing us with excess material to allow for wear and tear and as dysfunction of any part of the body, which we mean when we talk about sickness or ill health, can only be due to hyper or hypofunction of certain body tissues, we cannot expect to find dysfunction until the particular tissue involved has been reduced to the minimum it can carry on with satisfactorily.

Our recognition of this stage may be at a time at which dysfunction only shows itself when the particular tissue involved is called upon to do extra work or it may not be recognized until dysfunction shows itself under normal working conditions, under either of these circumstances gross damage has already been done. If we were dependent on the limited number of cells we were originally provided with, under these circumstance we should be in sore straits, but owing to the fact that many cells are capable of multiplication or have certain powers of regeneration when somewhat damaged, we continue to live. There is yet another important factor in the reestablishment of function. In the presence of bacterial infection, there is around the invading bacteria an area, which, owing to the invasion of leucocytes, tissue cells, etc., is temporarily put out of action, and which on the dispersion of these cells quickly resumes function. It is this process which gives us our most brilliant results in treatment. For instance, kidneys invaded by organisms from infected tonsils and showing a heavy cloud of albumin, often resume normal functioning in two or three weeks after tonsillectomy.

Of the few factors responsible for tissue dysfunction in the body, by far the largest is that brought about by bacterial invasion; when this takes place and long before we are aware of it notification is sent by certain means to those parts whose duty it is to attend to such matters. These messages may be conscious but in the majority of cases in chronic disease they are not so.

Impulses may be communicated from cell to cell, but if it is necessary to convey messages to a remote part of the body one of two methods is adopted.

They can be sent along certain tissues which have become specialized for that purpose or they can be notified by secretions discharged into the blood stream. Of a necessity such secretions are the result of cell activity. There is no other way that we are at present aware of.

Owing to its being necessary for many organs to be able to diminish their function as well as increase it, a double nerve supply will be necessary. One nerve alone may be able to increase function which on ceasing to supply stimuli will allow function to return to normal level. This may suffice for certain organs or tissues, but for many two are necessary.

Every action and reaction within the body, except voluntary movement, is dependent upon the integrity and smooth working of these nerve paths and tissues which secrete hormones.

If we take some primitive organism we find that certain cells are employed for motion, some for acquiring of food, some for digestion, some for getting rid of waste products, some propagation and some for protection. These primal tissues although becoming very complicated in higher forms of life always retain their primitive functions however complex they may be. For instance, the defense mechanism of some low organisms may consist of barbs on springs curled up within the cell which are released on touching a trigger. From such a type arose the wonderful mechanism which has to deal with the hundred and one dangers which assail mankind, whether it be man, beast, bacteria or any other menace. The involuntary nervous system with its antagonizing relationship is divided into sympathetic and parasympathetic groups. The tissues from which the hormones are derived are likewise divided into two groups, one siding with or supplementing the sympathetic, the other the parasympathetic. With the sympathetic go the thyroid, the adrenals, pituitary and gonads, with the parasympathetic go the parathyroids, thymus, pancreas, spleen, liver, and possibly others.

We have the sympathetic and its auxiliaries taking control of all matters pertaining to defense and self-preservation against factors potential for harm. It likewise controls the factors by which man is able to procure his food and also presides over the reproduction of species.

The parasympathetic and its auxiliaries preside over the assimilation of food when once procured; they also control the elimination of waste or harmful products. This is very obviously illustrated in the intestinal tract. It is then clear without going too deeply into the matter that all automatic selfregulating mechanisms are under the sway of these two great systems.

When either of these systems is working normally nothing is felt, there is no disturbance within the body, but when called upon for excessive action certain definite symptoms are produced, which will occupy our attention. We as medical men are very dependent upon symptoms to assist us in our diagnosis of disease and unless we have a clear conception of these symptoms we are not going to be helped by them very much.

Owing to the fact that all messages in the body, except voluntary ones, are carried by one or other of these systems, it therefore follows that all symptoms except such as are the result of direct damage to tissues are the result of the functioning of one or the other of these groups. There is no other possible source. If we grasp this thoroughly it will be of inestimable help to us in diagnosis and treatment also. We thoroughly understand that if we have destruction of the islands of Langerhans or our kidney tissue destroyed or put out of action temporarily we shall have signs of the resulting dysfunction. These symptoms are more or less clear, but there are many the origin of which are not so clear, and it is the purpose of this paper to try and lay bare some of these and at least point the way for further investigation. As originally pointed out, the biggest factor we have to deal with in dysfunction of tissues is bacterial invasion. Where there is this invasion the sympathetic and its auxiliaries are brought into full action. These symptoms are so marked that he who runs may read, and can usually be recognized as soon as the patient walks into the room. They are common to at least fifty per cent. of patients attending my and anybody else's outpatient department. They call aloud for the relief of infection. They are known to all, but all do not know their significance. They are shown at their best in an extreme case of exophthalmic goitre. Every single symptom is some exaggeration of the functioning of this group and not, as many believe, signs of hyperthyroidism; in fact there are more signs of hypersympathetic activity than overaction of the thyroid. It is impossible for one part of this system to function without bringing in the others. If you remove the superior cervical ganglia very similar results are obtained as removing a large part of the thyroid. This is a good answer to those who say that all the symptoms subside in exophthalmic goitre when thyroidectomy is thoroughly performed and therefore the thyroid is the cause of the disease. These symptoms in mild cases may be nothing more than slight nervousness, a little increase of the pulse rate and a heart that is easily accelerated. They are often accompanied by a tremor, a feeling of lassitude, an inability to sustained exertion, and often a visible thyroid.

I wish here to deny the existence of the socalled physiological enlargement of the thyroid. It is the surest sign of infection there is. Nervousness likewise is also frequently a sign of infection. Not everybody shows signs of nervousness when they come to see a doctor, but a great number of infected persons do. Besides the sympathetic nervous system being in hyperactivity, bacterial invasion will be responsible for numerous impulses passing to the central nervous system which will likewise accentuate nervous activity, an accentuated response to all stimuli being the dominating element throughout.

All these symptoms are well known and have been admirably portrayed by Langdon Brown, but all do not know of their relationship with the milder and chronic infections.

When we find these two big systems unbalanced, as we do when thyrotoxic or anaphylactic phenomena are in evidence, how are we to read it. Are some people constitutionally so disposed to one or the other by inheritance or has prolonged exhaustion of one or other of the systems been the cause of the lack of balance? We do know that people are easily divided into three classes, the highly strung, the phlegmatic and the normally balanced individuals. Being born

of highly strung parents undoubtedly predisposes to the condition in the children, and in just the same way we find whole families with symptoms of pituitary dystrophy with a tendency to fat and a lethargic temperament. On the other side let us consider the child who starts early in life with infected tonsils as undoubtedly the mother infects them at a very early age. This child will have its defense mechanism constantly employed. The result of this will be a nervous system, with the sympathetic dominant. Night terrors will often be the initial trouble; this means fear, and once fear enters a child's life the possibility of a stable nervous system being established is very improbable. It is quite unnecessary to depict the highly strung child who is so well known to all. Later on if this hyperactivity of the sympathetic system is unchecked neuroses, hysteria, eroticism and neurasthenia are likely to follow.

On turning to the other group, things are not so clear, as less thought seems to have been expended in this direction.

If we depute the assimilation of foodstuffs to the parasympathetic group we may without hesitation include the elimination of waste and harmful products also, and I do not think that this can be denied, the elimination of all harmful and waste products. This covers a big field and involves a great responsibility upon this group, yet I see no way of its avoiding the obligation. In the primitive organisms the few cells which undertook elimination have in man developed into this vast system with all its ramifications. If man ingests some harmful product his parasympathetic system causes him to vomit. If he has within his body certain poisonous substances certain kinds of symptoms are produced; these symptoms are more or less constant irrespective of the substance producing them. They are not the result of tissue damage so must of a necessity, as previously explained, belong to the parasympathetic system in action.

We are still very much in the dark concerning these matters, but if I can tack anaphylaxis and parasympathetic phenomena together, it is only a matter of time for the rest slowly to evolve itself.

Vomiting and diarrhea then are the first and most primitive methods of elimination of harmful products, and are purely vagal stimuli; this is best illustrated by what is commonly known as seasickness, where there are streams of vagal stimuli passing from the semicircular canals. Tobacco poisoning causes vomiting, not because there is anything in the stomach of a poisonous nature to eject, but purely by excessive vagal stimuli. Asthma perhaps is one of the best recognized anaphylactic phenomena we know of. It is chiefly characterized by spasm of the bronchial muscles, the result of vagal stimuli. The accompanying engorgement is perhaps difficult to account for as neither vagal or sympathetic stimulation cause any alteration of the blood flow through the bloodvessels of the lungs. Urticaria and localized swellings as angioneurotic edema are also well recognized by many as anaphylactic phenomena and are frequently associated with asthma. A man presented himself at my outpatient department with angioneurotic edema of the face which had been moving to different parts of his face during the last week; he was also an asthmatic. Others have recognized this connection between the two. If one could link up localized edemas with the parasympathetic system my views in this matter would require no further evidence.

There is just one thought which may possibly throw some light on it. We are all aware of the condition known as localized sensitization, which after all is a provision for the destruction of bacteria and elimination of their foreign proteins. Now the local reaction to invasion of bacteria to sensitized tissues and urticaria following fish poisoning are practically identical. If one is undoubtedly parasympathetic, in view of elimination belonging to that group, so most probably must be the other.

With the urticaria following the parenteral introduction of a foreign protein the tissues are in a state of sensitization generally, with the introduction of bacteria to sensitized tissues the reaction is the same but local. In the latter we recognize the process as a useful one in the elimination and destruction of the bacteria and its toxins. Can we exclude the same mechanism as functioning in other forms of parenteral introduction of foreign proteins which are not localized but general?

The exact mechanism which causes the endothelium of the capillaries to allow the egress of fluids is not clear nor whether the stimulus comes from nervous or hormone influences. That it may be the local reaction to foreign proteins circulating in the blood is suggested by generalized urticaria following the local reaction of a serum injection. It may even be reasonable to conceive of its advent in a general parasympathetic reaction irrespective of foreign proteins.

Likewise it seems unnecessary for vomiting to be produced because fluid is moving about in the semicircular canals. What really happens is that stimuli are sent which produce marked reaction to the parasympathetic group whose primitive action is to produce vomiting; in other words all the resources are brought into action together like they are in the sympathetic reaction during bacterial invasion. With this in view we can then understand why urticaria should arise in other cases than those in which bacteria are invading sensitized tissues. It is simply one of the various phenomena of parasympathetic activity which may show itself during general reaction, and as such does not only occur in the presence of bacteria. Such a view seems reasonable.

The vomiting of pregnancy is probably on a par to that of seasickness. Defecation and parturition are parasympathetic acts. The uterine contractions of early pregnancy being more pronounced than formerly will stimulate the vagus excessively and the primitive instinct will be brought into play. There is also the possibility of an anaphylactic response from absorption of an unaccustomed protein in the desidua.

As either of these two great groups of symptoms is due to excessive action of one or the other group, that is, they are temporarily unbalanced, the obvious thing to do would be to balance them again if possible. In the case of hypersympathetic-parasympathetic activity stimulation of the antagonizing system should do away with the symptoms. Such is the case. This can easily be done by administrating the corresponding gland products, such as thyroid, suprarenal or pituitary extracts. The same end results can be obtained by depressing the parasympathetic system by drugs which have poisoning effect

upon it such as atropine. In our treatment of asthma we employ both these methods; we use belladonna and we also use iodides, which is only supplementing thyroid activity in the latter and paralyzing the vagus in the former.

Adrenalin quickly relieves asthma, but, owing to the liability of atheroma developing from its prolonged use, one does not like to continue it too long. A short time ago a patient came to me with asthma in a very severe form. He said that he reacted very badly to iodides, his eyes becoming much inflamed and that he could not take belladonna, and knowing that strychnine owes its action largely to stimulation of the adrenals, I put him on it. The next time he came to see me he was greatly improved. I then used thyroid extract as a better stimulus to the sympathetic group with still better results, but owing to a persistent antral infection I have been unable to rid him of his asthma entirely. Adrenalin relieves urticarial swellings rapidly. This alone should place urticaria within the parasympathetic group.

It has been known for some time that the prior administration of adrenalin prevents the occurrence of anaphylactic shock and relieves it when present. It is not at all uncommon to find a whole family with anaphylactic tendencies, some being liable to hay fever, others sensitive to some food protein; they will also often show the stigmata of the parasympathetic characteristics. I have had several asthmatics on thyroid extract for some time, and only in one who had an infected antrum which will require operation have I failed to bring about complete relief. It is well recognized that there are various foreign proteins responsible for asthma, but after a good many years of clinical experience I have rarely been able to find one which did not show marked nasal infection. An infected nasal mucosa means an irritable one which reacts to dust and almost any pollen, even a cold wind causing an acute outpouring of clear serum. I bring this forward as I feel we are inclined to regard these things too much as specific reactions when perhaps they are more generalized ones. I know a child who cannot ride her pony without her eyes and nose running profusely. I told her mother to give her two grains of thyroid extract daily; this did not cure her but considerably reduced the reaction. If we can establish the fact that all symptoms are either the result of impairment or damage to certain body cells or else due to one or other of these systems in unbalanced action a good deal of what was before obscure will become clear.

Epilepsy, on this basis, offers some chance for solution. It is a recognized thing that in some epileptics there are organic lesions and in others nil. With organic lesions, which are invariably the result of bacterial invasion, we can well understand fits resulting, but where there are no lesions it is not quite so clear, yet looked at in the light of the views already expressed some solution may be forthcoming. Urticaria is perhaps the commonest anaphylactic phenomona there is. We are quite familiar with its appearance on the outside of the body because it is obvious, but have we any reason to think that it is limited only to the skin? There appears to be no reason why it should not affect all tissues; certain forms of hydrops articuli and the congestion of the bronchial mucosa in asthma are in all probability due to such conditions, so we have some good grounds to consider the possibility of cerebral urticaria. The relationship of cerebral edema and convulsions is well known.

I have during the last few years been able to relieve several epileptics of fits by clearing up certain focal infections. This is understandable as the result either of removing a source of bacterial invasion or of removing a foreign protein. With bacterial invasion, if too much fibrous tissue has not been laid down there is some hope of good results, but when there is already much deposited little can be expected, but if it is a matter of eliminating a foreign protein then much can be hoped for. That bacterial invasion is a cause of epilepsy is shown by the fibrosis found. That cerebral urticaria is a cause has yet to be shown. If such be the case then some benefit may be got by stimulating the sympathetic group, but no cure will be established unless that foreign protein, bacterial or otherwise, be eliminated first. Harrower, of Glendale, California, has been advocating the use of anterior pituitary body with thyroid extract and has claimed certain benefits in a limited number of cases. Whether this acts by stimulating the sympathetic group generally or locally is not clear. I have found that calcium is likewise of great benefit to epileptics and calcium is supposed to stimulate the sympathetic system, but I do not know if its action is due to that factor. My present treatment is to eliminate all focal or specific infections and stimulate the sympathetic group. One must also test out all the likely food proteins which may possibly cause anaphylaxis, the same as is being done in hay fever, always bearing in mind that the foreign protein of bacteria is perhaps the commonest and should be first eliminated.

That the intestinal tract is liable to urticarial swellings is suggested by the severe attacks of abdominal pain and vomiting that certain people suffer from who are anaphylactic to shellfish, honey, eggs, etc., and on whom such swellings can be produced by intradermic injections of the specific protein.

Such urticarial swelling is akin to, if not identical with, that of hay fever and asthma where the mucosa swells, the one being patchy, the other diffuse.

In reviewing these points we find that there is hardly one symptom belonging to the parasympathetic group which is not controlled by utilizing some endocrine product of the opposite group. Wherever improvement takes place under such conditions, it is very suggestive that such symptoms fall within the parasympathetic group. The same applies to symptoms that are relieved by employing such drugs as atropine and its derivatives in paralyzing the parasympathetic group.

When we try to reverse the action we find things are not so easy, as the parathyroid and thymus of which we have extracts do not have the same counteracting effect as the sympathetic group. Some have found eserine useful in counteracting the sympathetic symptoms. Personally I have found emetine hydrochloride the most useful. Apocodeine, which is useful in laboratory experiments in animals, is not so beneficial in human beings.

With regard to the endocrine products of the parasympathetic group they have not to my knowledge been employed in trying to counteract sympathetic phenomena and perhaps when more investigation is

done in this direction some useful results may be forthcoming.

Within a few weeks of writing this it has just been announced that insulin is useful in counteracting the symptoms of exophthalmic goitre, which falls into place with the views here expressed and is on a par with the action of adrenalin in asthma.

Following on this comes the discussion on the nature and treatment of epilepsy, with the opening paper by James Collier in the December 6th edition of the *British Medical Journal* in which some of the ideas put forward here have already been investigated, but what interests me most are the few remarks by the president (Dr. Grainger Stewart) who considers that the cause of epilepsy may eventually be found to concern the vegetative nervous system. He described a case of epilepsy in a patient of the vagotonic type, with greasy, blotchy skin and offensive sweating, in whom the administration of tincture of belladonna (twenty minims thrice daily) led to a cessation of the fits and remarkable improvement in the general health.

The available evidence rather tended to show that the vegetative nervous system might overact from either the sympathetic or the parasympathetic side.

We have here an independent opinion tending to the same line of thought and I think helps to confirm the views expressed here. Fully realizing that a vast amount of observation and experimental work (possibly more observation than experimental work) must be done before these matters are finally cleared up, I offer these views with the idea of turning thought into the channels I have laid down in this paper.

The Phantasy Method of Analyzing Narcisistic Neuroses*

L. PIERCE CLARK, M.D.
New York

It is the main purpose of my thesis to show that the narcisistic neuroses may be analyzed by what I term the phantasy method. I have gradually evolved and perfected the technic of this method during my analytic work of the past three years, and it may be said to have its sanction in Freud's statement that persons suffering from narcisistic neuroses "do say many things but not in answer to our questions." It is to these free and spontaneous utterances that our proposed method particularly applies.

Theoretically, we have some conception that primary narcisism comes into being at the first independent activity of the fetus in utero. During this period the different organs and structures, and perhaps the beginnings of the psyche itself as manifested in sensations and instincts, are endowed with libido. What is termed secondary narcisism follows the subjective primary maternal identification of the infant's attachment to the mother at birth. At the weaning from the mother—who is concerned here in the broadest sense of the infant's whole outer world—the infant divides his libidinal attachment; a part goes forward to form an objective libidinal activity, and the part that is embraced in the autoerotic libido is turned in upon the developing ego and serves as the libidinal complement of the latter. This latter organ is attached to the perception apparatus of the ego, which is engaged in continuous testing of reality, and to that portion of it especially given over to the sex impulses, and is also attached to the activity of the ego impulses. A portion of this ego libido complement forms the narcisism, which in greater part cut off from direct reality testing, encourages the ego impulses to build an object world within its own inner world of concepts. The circuitous and devious path by which the narcisistic libido brings this about is the special province of a large portion of modern investigation in psychopathology today. Just how the primary identification is detached from the mother-imago, is repressed into the unconscious and reappears in symbolic or conceptual formulations of somatic and psychic patterns, is not yet fully revealed, but under the masterful direction and leadership of Freud and his coworkers such as Ferenczi, Rank, Abraham and Jones, it is being worked out. We are not at present directly concerned with their worthy researches, nor can we give attention essentially to the manner in which the several clinical patterns of narcisistic neuroses and psychoses have come about. Data covering this part of the subject are naturally even more obscure than the former. Rather shall we turn our attention to the state of narcisism in general as manifested in its neuroses and their possible analysis.

It is freely admitted that not only is narcisism a natural component in every individual, but that it serves a specific purpose and value in successful living. But when it is so quantitatively and qualitatively disproportionate that it fails to serve the ends of reality (sublimated) it presents itself under various clinical forms of neuroses and psychoses and immediately calls for our best efforts of alleviation. At the very outset we are confronted with the barrier of an absent transference leverage by which we may analyze the condition. But by the conscious will and a narcisistic transference we may accomplish something, as has been so excellently suggested by Wälder. His aim, if I conceive it rightly, is largely to present certain aspects of the narcisistic components, those most healthful by reason of their better adaptation to reality to the ego impulses derived from the *id,* and thus bring about a natural sublimation which, as Freud has shown, is possibly the way to sublimation, even for all libidinal conflicts. Ingenuous and valuable as his procedure is, I have undertaken quite independently another approach to the problem. Impressed with the fewness of early data of affective attitudes of all types of narcisistic patients and their highly protective and

*Abstract of paper read before the Ninth International Congress of Psychoanalysts, Bad Homburg, September 3-5, 1925. Complete text is in the process of publication.

specious rationalizations, and in the absence of free association of direct memory, I have instituted a phantasied recall of the infantile life itself, especially of the mother-and-child relationship in the primary subjective maternal identification period. If this period is the crux of the secondary narcisism, the very foundation of the later narcisism, then all means of its recovery in any form must be of value in gaining knowledge of the formation of the narcisistic attitudes, feelings and thoughts of adult life.[1]

At the very outset I wish to disclaim that the phantasied material I have reproduced is a facsimile of actual memories of infantile experience. To do so would naturally stultify all our present psychologic knowledge of this epoch. But I do maintain that these phantasies throw a flood of light upon the affective states during these infantile reactions in the secondary narcisism of mother-identification and the integration of the character and personality consequent thereto. The phantasies are therefore psychologically true if not actual memory reproductions of this period. They are, moreover, worthy of continued investigation in narcisistic neuroses. Furthermore, the method for resolving various forms of narcisistic disorders—such as dipsomania, homosexuality, melancholia, essential epilepsy and confirmed stammerers—has so far as used been surprisingly satisfactory.

THE PHANTASY METHOD

In order to avoid the protective mechanism that lies within every narcisist, and in the absence of the transference which these subjects are unable to establish, I have instituted the phantasy method. In effect, this is comparable to inducing a mild self-hypnosis. It may not seem unlike a form of day dreaming, or certain phases of psychogenic hallucinosis in which mild degrees of clouding of consciousness obtain. This procedure brings about a certain disorganization of consciousness, and, moreover, the displaced primary personality of the narcisist is enabled to gain the power of insight into the intricate pattern of the narcisism which has been built up from the identification with the mother, in the exaggerated and enduring dominance of which it owes its power and sway over the entire life of the individual. The form of transference which is finally evolved is, of course, essentially narcisistic or of the parental type rather than the lover, which so universally obtains in the transference neurosis.

The physical situation for phantasial analysis is not dissimilar to that in ordinary analysis,—couch, reclining posture, etc. The patient is directed to close his eyes and face away from the analyst. He is then requested to imagine or phantasy the subjective feelings, attitudes and behaviors of an infant preferably from the first day of birth. Commonly but little or nothing is produced in the first few seances. The patient is discouraged and somewhat bewildered in analyzing in this manner without the factual data of the dream and association method. Soon, however, the phantasial material gradually changes from a stilted and reportorial fabrication to matter that is shot through with instances of emotional feelings of the infantile life. Often the patient is inclined to believe they are actual memories. After a little he usually comes to the realization that they are automorphic retrojections having all the affective values of infantile memories, bearing their emotional insight as to the formation of specific attitudes, and finally bringing to light the more definite narcisistic fixations upon oral, anal and urinary eroticism, the direct outgrowths of the nursing act and the weaning trauma. The infantile utilization of these erotic fixations as magic behaviors is the very beginning of the narcisism. Continued analysis of these primary fixations enables the patient to trace step by step the successive orders of repressions and the repeated reappearance of more complicated object, aims and ways of thinking of his whole mental life. The most complicated systems of concepts which result from the unacceptability of the infantile magic ideas to reality are woven into the behavior and ways of thinking of these patients. They operate their entire lives upon these distorted patterns, the divesture of which comes about slowly through the new insight of phantasy analysis. The exact delineation of these behaviors has for decades been the chief object of descriptive neuropsychiatry.

The keenest conflict imaginable continues in the ego between the displaced portion of the personality and that part of it which is given over to identification with the mother. The rupture of the autoerotism of nursing causes the identification to fixate deeply into the erotic patterns of infantile magic surrounding the oral, anal and urinary functions. Perhaps the adult ego draws its power largely if not solely from the strength of the remaining unidentified part of the personality, and the infantile magic that gives color and depth of feeling is largely derived from sublimations of the identification portion. Only time and more patient investigation can clear these points. At any rate, in the ego neuroses the conscious desire to recover, plus the narcisistic transference added to it as it not infrequently is with object libidinal transference, are our talismanic advantages to illumine and subdue the narcisism formed from the maternal identification, especially those parts that are so prejudiced to instinctual sublimations.

To revert to the clinical technic of the method for a moment, the analyst may resort to an active therapy of creative art engrossment for the patient both before and during the analysis. The patient must, however, find these occupations for himself and continue to control them. The refined and elusive narcisistic disciplines of the analyst have no place in the uses of the phantasy method. The patient has his first chance in the interpretation, and it is surprising to note how little the complicated terminology of psychoanalysis is necessary for the patient to work out his salvation. He is not didactically or technically wise but recovers without zeal or propagandic tendency.

Only by fashioning and refashioning the different angles of insight into the conceptual behavior of this internally conceived world of the narcisist may the patient finally reconstruct a true picture of his dilemma, and he will act upon this new insight just as soon as it is deep enough to release the repressions and fixations. The aggregations of conceptual symptoms which the narcisist brings are but distorted

[1] In all my initial studies of the significance of the primary identification with the mother I am indebted to Burrow's work in this field which has helped so materially in our comprehension of the essential foundations of ego development and its perversions.

symbolizations of the cruder infantile patterns of magic needs drawn from the unsatisfied longings of the weaning period. They often disappear like mist so soon as the narcisistic transference is established, a restoration of the comfort producing state of attached nursing. Thus the real neurosis is at last revealed made up of the components of castration fears, inferiority, sadomasochistic, oral, anal and urinary erotism. These, then, are the defective states which the phantasy method uncovers. In brief, the birth and weaning process and their libidinal significances all come into being again. Many patients are reduced to the veritable defenselessness of infants and may for a time complain bitterly of their worse plight. Rather should the latter state endure longer so that the narcisism may gain a fuller cathexis and not reform so soon into a somewhat similar pattern to that of the old one. The very primitiveness of the narcisistic pattern precludes any rapid analysis as has long since been fully noted by Freud and his coworkers. The resistances are really enormous.

At some point during the treatment, most frequently at the beginning, occasionally a patient who either too perfunctorily produces his phantasial material or is too deeply engrossed in the mere detailment of it, will grow negligent in keeping notes of the exact previous analysis which every patient is requested to make. Time after time he will appear for analysis without them, and although he has been told it is a matter of routine that he bring a transcript of the previous interview, each day he will say that he thought after the main thoroughfare of infancy was demarcated further notes were unnecessary. Though reminded that such is not the case he will persistently skip many sessions; these elided ones are always significant and worthy of analysis. Still later, many patients grow restive and complain that knowing they must bring in a written record they feel that the procedure "cramps their free style or analysis." Long and elaborate defenses of their resistance to writing notes are often forthcoming seemingly made with the best of reasons. But on specific analysis one finds that these very specious resistances are but a part of the narcisism and the patient's unwillingness to do his share. It is as though the patient unconsciously made use of his infantile reactions and said to himself: "Now, I will tell mother (the analyst whom he has invested with narcisistic transference) all my troubles, and as to her asking me to fulfill my part by doing any work, well, she will excuse me I know, for she loves me, she will understand that it is really too great a task." This species of resistance is far from any ordinary malingering desire to be let off from work in analysis and is not dissimilar to like resistances to the routine of ordinary analysis. It differs from the latter in being much more plausible and cleverly rationalized. As is usual, such formulations of narcisistic resistance are found to be a storehouse of similar attitudes in all the life reactions.

Many patients term case notes "a monotonous, disagreeable task," yet they talk daily, on and on, about their most intimate infantile experiences which their intelligence must tell them are the most tedious topics imaginable to the analyst, yet rarely do they thank the analyst for his forbearance beyond a fair monetary compensation for service. Perhaps none who do not feel a mother's loving concern could afford to labor at such a monotonous task at such a low remunerative rate, and as parental love the patient reckons it. The patient makes a bold statement of the "stale unprofitableness" of casenote return, but by what other term can the object-libidinal world be better designated? As Wälder aptly comments, "To the narcisist the outside world means far too little for him to give its laws sway over his mind." Many patients try to relieve the situation by making something literary of their reports in order to add to their lustre and worth, and put in quotations of a wide discursive sort which are of doubtful illustrative moment. When duly requested to keep an accurate account with no embellishments save for marginal notes of other pertinent data which have occurred to them in the process of recalling an interview, they are much disturbed and chagrined. But even the more free phantasied analysis has its disciplines, not in the matter of interpretation of material, for that is a process of spontaneous and slow awakening on the part of the patient, but rather in his submission to the technic which lies at the root of all good science and art.

In my complete text I give one or two illustrations of patients who previously were unable to give any data earlier than four or five years of age, to show what a wealth of phantasy is presented for continued analysis drawn from this infantile period. The following was preceded by the phantasy of infantile life. No sooner had the procedure been established after two seances than the patient "broke through" into the sequential socalled personal or actual memory recall. Although this, too, is probably an automorphic retroprojection, it is given in all the emotional coloring of a real memory. We may say, therefore, the material is psychologically true.

Example—Miss F. B. "During the analysis, as I attained a state of physical and mental composure, all thought processes seemed to cease. A thick, velvety darkness seemed to settle down over me. My whole being was permeated with a delightful sense of warmth and comfort. There was no localized physical feeling. There was no differentiation of the parts of my body. I was a complete whole—warm, suspended in inky darkness. I was conscious of moving but the movement was accompanied by absolutely no effort on my part. It was a smooth swinging motion. There was no emotional feeling, simply a state of heavenly comfort, warmth, motion, no effort. Then a sudden feeling of cold. The velvety darkness was gone. I was conscious of something rough and cold on my body—hands, I suppose. I was uncomfortable—I seemed to want to protest against the light, the handling—I cried——.

"I see a baby lying in a little white crib cooing and waving its hands aimlessly about. Now a strange feeling of delightful contentment steals over me; there comes an impulse to move my hands before my face, to utter cooing sounds of pure comfort—why, I am that baby! The ceiling and the walls of my crib are the boundary of my world, and my world has no flaw——. Now, there is a vague sense of things not being just right—I am not so comfortable. I seem to know that if I cry the situation will be remedied. I hear footsteps—my hands

and feet move—I am trying to express my eagerness, my joy for what this beautiful person is going to do for me. She picks me up and moves from the crib to a chair. Soft arms hold me close, and now there's something soft and white above me—that's what I've been wanting, what I've been waiting for. It's in my mouth, warm and soft and round. There is a pressure and release of my tongue against it. Something warm and rather sweet in my mouth and I swallow. What bliss, and it comes without effort. It isn't difficult to move my lips and tongue. I didn't learn to do it—it simply is a part of me and this person with the beautiful face who bends over me is the one who gives me this part of myself."

This is but a sample of actual working data supplied by the phantasy method; the complete text presents the whole matter in elaborate detail. The results in general of the use of the phantasy method are in proportion to the completeness of the libidinal recall in the formation of the narcisism. The form of transference is quieter, and the patient gains a power of insight that is most noteworthy.

As Schilder states, the limits of these behaviors which the perceived real world portends to the imagined actual world (the world which is comprehended only by concepts) are not drawn too sharply. Even the world of phantasy is extremely near the actual world.

I may summarize the main contentions of my thesis:

1. That from the subjective identification of the child with the mother we have the beginnings of narcisism which in its undue and enduring magic-like dominance entails various narcisistic neuroses and psychoses.

2. That by the phantasy method under a narcisistic transference we are able to recover the psychologically true values of this secondary narcisistic period and thus induce a real insight and sublimation of so much of the narcisism as may be necessary for the well being of the individual.

3. That from illustrations in my main text I have made a successful beginning in the phantasy analysis of narcisistic neuroses and psychoses such as in melancholia, dipsomania, essential epilepsy, confirmed stammering and in general narcisistic neuroses without specific category.

DISCUSSION

Dr. Paul Federn, of Vienna, said he would refrain from entering immediately into a discussion of the theoretical conclusions reached by Dr. Clark. His paper emphasized the earliest relations to the mother as the most important feature in the development of the narcisism and as the stage in ego development upon which the strongest fixations, normal and abnormal, are regularly maintained. The technic which the author used with his theory as a foundation, was a fully orthodox Freudian psychoanalysis. It was even, as Dr. Clark himself said, a sort of over-analysis, because the normal pschoanalysis is, really, a method of communication between the patient and the analyst, while the phantasy method is purely a monologue on the part of the former. We generally have used fancies and day dreams as we use dreams; that is to say, as material to be analyzed by way of free association, starting from the single image or element of the phantasy-product. But some of us have already observed, and Rank has applied this as a method, that the producing of dreams is, itself, some sort of abreaction and causes some degree of readjustment to take place. In the same way, the phantasies systematically produced in the phantasy analysis are of value because of the liberating and remedial effect which they have on the narcisistic personality in case that personality is unable to make the transference, which is necessary for the communication of free associations. It seems to be an important and valuable improvement of method to indulge completely narcisistic personalities in their narcisistic tendency to introversion, in which they go so far as to phantasy that they actually return to their earliest stages of narcisistic perception of the external world, stages which—as Dr. Clark said—go back to their second and first years of life.

At this point he wished to lay stress on the difference in this method as compared with the advice given by Freud. Freud says that it is our task, in psychoanalyzing, ever and again to lead the patient from repeating the past to reenacting the past. The patient will relive his past conflicts and desires in the transference, with the analyst. By overcoming the resistance transferred to the analyst, recollections of the real events themselves and of the situations come more and more to the surface. All this difficult process Dr. Clark tried to render superfluous and to a certain extent he succeeded in doing so. He resigns himself to the absence of transference and is satisfied if the patient reproduces his past in fancies. The difference in the two technics is striking but it does not affect the essential points of psychoanalysis. Dr. Clark was led to his method by the type of his group of patients who were narcisistic and without the amount of object libido necessary to act as a solid carrier for the transference. Freud said long ago that for the narcisistic diseases the usual method of psychoanalysis would have to undergo some alterations. Just such an entirely legitimate alteration is supplied by the phantasy method introduced by Dr. Clark. It makes a circuit, necessitated by the introverted libido of the patient, and tries to make use of the patient's narcisism itself in order gradually to attach to the silent hearer of his fancies the minute quantities of object libido (sometimes this object libido is, in the beginning, only an exhibitionistic one) which accompany every narcisism. If one understands and accepts the method adopted by Dr. Clark, with the intention of stealing into the narcisistic entrenchments of such patients, one will not be surprised that some of the technical rules of psychoanalysis are completely neglected. Dr. Clark does not require the patient to keep fixed hours, and does not interrupt the patient so long as he is in the mood "to remember" by producing fancies. His method of conducting analysis is the natural result of being without the transference. The individual relation to the analyst is of so little importance in the proceeding that no agreement between patient and physician need be established. The way, however, gradually to attach the interest of the patient to the analysis and to the analyst, and indeed to have the opportunity to analyze at all, is to make the rule that the patient shall write down the contents of the last session before coming to

the next. In this literary reproduction of the fancies ingeniously produced, the patient must think also of the one who is to read them, and begins to devote his interest to the task of writing, as well as to the analytic questions and explanations he has to expect from the analyst. Sometimes this writing is—as in the first year of school life—a means to develop an interest in the idea of "working" at all. This variation of method is well adapted to the difficulties offered by the narcisistic cases. In every psychoanalytical treatment it is necessary to satisfy to a certain degree those libidinous tendencies and desires, the denial of which, the *versagung,* started the morbid reaction and established the neuroses. This is necessary so that the patient can overcome his resistance against bringing forward into the conscious mind the repressed parts of his life and of his personality. In the normal method the positive transference and the negative are used to invest the readjustment with the maximum of satisfaction. When narcisism prevails, enough of the unsatisfied narcisistic needs must first be satisfied in psychoanalysis before an analysis can work at all. This seems to be made possible by respecting the patient as a completely narcisistic person until he has once more lived through the original narcisistic period of his life, lying and producing fancies, behaving like a suckling, but with an attentive listener at his side.

Dr. S. Ferenczi, of Budapest, said he wanted to express his interest in the success Dr. Clark described as the result of his treatment of narcisistic neuroses. His own efforts in this respect were far less satisfactory. As Dr. Clark read his communication, however, he gained the impression that his method was rather the suggestion of a special phantasy or phantasies. At any rate, it has more to do with abreaction method of Breuer and Freud than with the thorough investigation of the whole libidinal and ego development which is the present psychoanalytic method.

Dr. Clark (closing) said he was glad to know that Dr. Federn, with all his knowledge of psychoanalysis so valuably collected from the researches of Freud and his coworkers, and especially with his experience in the transference neuroses, was so clearly able to visualize the main principles of the phantasy method and give his approval to it as a matter of analytic procedure worthy of respect and continued trial in an attempt to unravel the mystery still surrounding the narcisistic neuroses. As regards Dr. Ferenczi's remarks, Dr. Clark did not believe that Dr. Ferenczi had understood the full purport of the paper which had been so briefly presented in abstract when Dr. Ferenczi said that the method only looked toward the analysis of some very special or suggested phantasies and was therefore not broadly psychoanalytic and thus failed to make a thorough investigation of the whole libidinal and ego development. Dr. Clark's paper stressed the whole infantile life in all its libidinal connections for at least the first few years of existence; what could be more thorough or broadly psychoanalytic? There was, perhaps, some justification in Dr. Ferenczi's statement that the method was akin to the former method of Breuer and Freud, but it was more than a catharsis of conscious and foreconscious material but actually brought up indubitable data from the painfully repressed infantile life that has a remarkable verisimilitude in content with the pregenital unconscious material only inferentially arrived at by former psychoanalytic interpretations. Both data he held to be psychologically true and each had their unique advantages. When obtainable by the phantasy method is was so much more abundant and easily brought into consciousness and moreover had been produced in cases absolutely intangible to any known technic of ordinary analysis. Only further investigations would determine its full curative utility and as a beginning he offered it for general psychoanalytic use as part of or supplemental to our present psychoanalytic technic. He was glad to know that several of the members of the organization had expressed their intention to try out the efficacy of the method in their own cases.

2 East Sixty-fifth Street.

Diverticulosis

CHARLES J. DRUECK, M.D.

Chicago

(*Concluded from page* 88)

2. The result of incarcerated concretions and gaseous distention varies from slight abrasion of the mucosa to perforation through the wall of the sac and may set up an abscess localized to the tissue outside the sac. Such an abscess will gradually enlarge until it bursts into the bowel through the original opening connecting the intestinal lumen of the diverticulum, or the peritoneal cavity, or on to the surface of the abdominal wall. It may become adherent to the bladder and burst into that viscus causing a colovesical fistula. Or as the result of some sudden increase in pressure the ulcer may burst suddenly into the peritoneal cavity and the resulting escape of material from the bowel will then cause a general peritonitis. Abscesses have formed in the intestinal wall, outside the wall surrounded by coils of small intestine, in the mesentery and extending to the liver and left kidney. Abscess formations have simulated carcinoma. Fistulous tracts have resulted between the sigmoid and the small intestine and the abdominal wall. In some cases the fistulous communication may be direct between the diverticulum and the viscus, although, oftener, it occurs by way of an interposed abscess cavity. More than one perforation has been observed in multiple diverticula.

3. Acute or gangrenous inflammation may occur with symptoms so simulating appendicitis as to suggest a transposition of the viscera.

4. The most constant pathological finding is the chronic proliferative extramucosal inflammation. This chronic process following infection is an inflammatory reaction due to leakage of toxins or bacteria through the mucosal layer of the diverticula. It is usually accompanied by inflammation of the diverticular mucosa, but this is frequently not advanced and in some cases is indiscernible. Wilson (46) and Telling (47) have both emphasized the essential rôle of this process and designated it peridiverticulitis. In McGrath's collected twenty-six specimens presenting peridiverticulitis there were only five where the mucous membrane of the diverticula was extensively involved, in nineteen the inflammation varied from mild to a moderate degree, and in two it appeared intact.

TENDENCY TO CARCINOMA

This inflammatory condition is accompanied by the deposit of large masses of fibrous tissue, movable or fixed and further adhesions in the neighborhood of the diverticulum. This increasing mass of fibrous tissue will seriously stenose and angulate the bowel. In some cases acute or chronic obstruction has been produced in the small intestine. The sac wall becomes thickened and firm, and as a result of this and the deposits of exudates (round cell infiltration) and cicatrical tissue around it, a dense elastic tumor is formed, which later because of its size, form, consistency and macroscopic appearance is frequently mistaken for carcinoma.

Of gravest importance is the frequency with which carcinoma is implanted on the inflammatory process of acquired diverticula even without ulceration of the mucosa. This tendency to carcinoma occurs particularly in diverticula in the sigmoid. In McGrath's twenty-seven cases, carcinoma was present in seven (25.9 per cent). All of these were cases of advanced peridiverticulitis.

In considering this percentage (25.9) however, it is of the strictest importance for us to distinguish between the occurrence of diverticula in general, many cases of which are discovered incidentally at autopsy, and cases of diverticula with pathological processes so extensive as to give pronounced symptoms. In McGrath's cases the inflammatory changes were advanced, a mass was present in each and the symptoms were marked. Therefore, it is in such cases as these alone that the per cent (25.9) of carcinoma is to be considered.

That irritative conditions such as are present in these infections of intestinal diverticula are contributing causes of carcinoma, is a view supported by the observations of several authorities. Among the causes cited are chronic inflammation, cicatrices, bacterial irritation and trauma. From evidence based upon over 1,200 personal observations, W. B. Coley concludes: "Local trauma of any kind from chronic irritation to a single local contusion is not infrequently the direct exciting cause of malignant tumors of all types."

A consideration of this pathology is important to the clinician inasmuch as it indicates that symptoms are not to be expected at least in the early stages of the process.

PATHOLOGICAL ANATOMY

Gross appearances, external aspect.—The tumor is usually round or ovoid in shape, the smaller diverticula being oblong with the long axis transverse the bowel. Its surface is lobulated with many prominences varying in size from minute specks to that of a small cherry. The whole surface having a mottled hemorrhagic appearance. In some cases the surface presents a ribbed appearance, the elevations running parallel with the fibres of the circular muscular layer and suggesting a bulging of the mucosa between the bundles. These elevations are more numerous and largest near the bases of the appendices, epiploicæ, at the mesenteric border, or between the layers of the mesentery.

By dissection McGrath has found that the prominences correspond in general to those points where the vessels disappear into the muscular layer of the intestinal wall. The entrances of the larger vessels are commonly noted near the edges of the longitudinal bands, sometimes inside the edges, between widely separated bundles of the muscular fibres. The entrances of the small branches are variously situated on the haustra.

Each set of vessels is covered with a band of fat, which in the case of the larger branches, is continuous with that of the mesentery and terminates as an epiploic appendix in close relation to the vascular entrance.

Internal aspect.—On the mucosal surface are noted round or oval openings, and in others short transverse clefts. From these points plugs containing gelatine may be expressed and then thin walled pouches demonstrated. These openings on the inner surface corresponded in location to the elevations on the outer surface. Histological examination confirm the experimental and anatomical observations as to the common association of these processes with the course of vessels through the intestinal wall.

Examination of the muscular coat of the large bowel showed that the longitudinal layer, excepting in these bands, is usually very scant or entirely wanting and that frequently the circular layer is thin, its bundles separated, and its structure deficient.

In some instances microscopic examination reveals beginning projections of the mucosa and submucosa between widely separated bundles of the circular muscle without vessels directing their course.

There is occasionally a marked bulging and thinning of a sacculus especially in the lower part of the sigmoid where sacculations of bowel are smaller.

Microscopic examination of sectioned diverticula walls show them composed of mucosa, submucosa and remnants of muscle fibre, but in some instances only the inner and outer tunics are demonstrable.

In the study of a diverticulum of the sigmoid which was undergoing cancerous change, Mellon found on sectioning the entire tissue and carefully examining each section that one presented a suspicious area. This manifested itself by an interruption of the integrity of the mucosa, which in other places was sharply delineated from the underlying muscle. The limiting margin changed to scalloped where the growth became invasive.

Microscopically there was a steady increase of atypical tubules until the definitely carcinomatous area was seen.

The atypical character of the cells was recognized in part by their very hyperchromatic nuclei noticeable particularly in the lower levels of the affected glands. This abnormality, however, did not respect even the superficial portion of the tubules as the carcinomatous portion of the tissue was approached.

A well marked, round celled infiltration was present throughout the diverticulum, being particularly well marked in the atypical portions. It was present beyond the muscle walls, in some granulomatous tissue—peridiverticulitis. It is of note that all layers of the gut participated in the angulation process, but the mural layers, although everywhere present, did not always follow the tortuosities of the mucosa. The spaces enclosed by the sinuosities of the latter were usually shown to have definite connection with the lumen of the intestine.

In explanation of the frequency of malignant transformation in these cases, it is noteworthy that an apparently significant combination of contributory causes is here present. In support of the theory that "tissue tension alteration" is an important factor in neoplastic initiation, it would appear that in diverticulosis we have an example par excellence.

In the complete type of this condition, the labyrinthine windings of the mucosa, together with the obliquity and consequent separation of the muscle bundles, bear testimony to the interstitial strains that must be the resultant of these processes. And in mucosal hernia as it exists in a viscus, more or less constantly contractile, interstitial strain must again be unavoidably associated with histopathological changes in evidence, viz., passive congestion, hemorrhage, and dilatation of the incarcerated gland structures.

Nutritional disturbances are the logical sequel of this mechanical stress, which in their turn invite infection, a factor of neoplastic importance.

SYMPTOMS

Opinions vary concerning the etiology and pathology of diverticula and therefore a clear conception of the symptomatology is wanting. Owing to the definite clinical aspect, early stages of inflammation have been overlooked or misinterpreted. Its advanced stages have been diagnosed as malignant and consequently deficient treatment employed.

Sacs may remain inactive for years or at any time become infected and inflamed, causing symptoms frequently mistaken for appendicitis, peritonitis, chronic intestinal obstruction, new growth or pelvic abscess. That definite symptoms are absent in almost fifty per cent. of cases is indicated by the frequency with which diverticula are unexpectedly discovered during röntgen ray search or necropsy.

The following statistics compiled by Telling show that in 13,068 necropsies diverticula were discovered eighty-three times, of which thirty-nine were congenital, or true, and forty-four acquired or false.

TABLE I. OCCURRENCE OF DIVERTICULA

Boston City Hospital.....	1,382	11	1	1
Bender Hygienic Laboratory	953	5	0	3
Total	13,068	39	16	28

Their importance depends almost entirely upon the part of the alimentary tract affected. In the small bowel they cause, as a rule, no trouble, and are only discovered accidently, but in the lower half of the large intestine they are a most important clinical condition. It also happens that the pelvic colon is where they most frequently occur.

The character of the contents of the diverticulum determines whether it remains symptomless or not. The small intestine is filled with fluid material while in the lower part of the colon the contents being semisolid or firm, tends to be retained, and to set up secondary changes in the walls of the diverticulum. It is important to realize that the diverticula themselves are not harmful, it is the fact that they retain old fecal material which is the cause of possible trouble.

Diverticula more often occur in middle or later life and as a rule, but not always, in obese persons.

Statistical data of cases operated in at Mayo's Clinic from May 1, 1902, to January 1, 1912, show:

TABLE II.

Number of cases	27
Twenty-five specimens were obtained from operation, one from autopsy. One case was drained; surgical diagnosis, diverticulosis.	
Sex,	
Males	21
Females	6
Age,	
Youngest	40
Oldest	73
Average age	54
Operation,	
Resection	21
Partial resection	4
Ileocolostomy	1
Drainage	1
Location of initial disease,	
Sigmoid	20
Sigmoid and rectum	1
Rectum (at anal ring).....	3
Hepatic flexure	2
Descending colon	1

The symptoms of diverticulosis of the large bowel are analogous in many ways to those of appendicitis, except that the location is less constant. In the early stages patients complain of abdominal uneasiness, discomfort and sinking sensations, digestive disturbances, moderate constipation and gas accumulation.

Later when the inflammation has extended deeply into or through the diverticulum (peridiverticulitis), localized tenderness and cramps are complained of, with marked constipation alone or alternating with diarrhea, the sensation of blocking, fecal impaction and painful, indefinite swelling in the sigmoid region (left sided appendicitis). The symptoms are often subacute and accompanied by a moderate rise in the temperature, seldom above 102°. In a few days the pain, tenderness and swelling may subside and in two or three weeks the patient recovers. Wilson has shown that the symptoms are seldom those of diverticulitis but more often of a peridiverticulitis.

In the severe cases when the bowel is almost occluded there is marked gas and fecal retention, severe pain, muscular rigidity, nausea and vomiting, obstipation or coprostasis, diarrhea, leucocytosis, increased pulse rate, irregular or high temperature and (when the diverticulum is infected) there is mucus, pus or blood in the stools.

Abscess formation may develop with spontaneous rupture, most frequently through the bladder. This may result in a permanent vesicosigmoidal fistula. When perforation of the ulcer takes place into the peritoneal cavity a spreading peritonitis appears. At such times the Ochsner treatment is to be carried out until the acute condition subsides to a chronic state. Between the attacks symptoms and size of the tumor diminish and the swelling is smaller when the sac is temporarily freed of gas, feces and pus.

Fistulæ between two portions of the intestine may occur and rarely heal spontaneously. Occasionally they lead to the formation of other abscesses which may rupture spontaneously with the formation of multiple fistulæ.

CLINICAL DIAGNOSIS

In reviewing the clinical aspect of cases cited in the literature it is instructive to note the possible errors in diagnosis and the gradual increase in clinical recognition of diverticular infections by those whom experiences with several cases has impressed.

Diverticulitis and peridiverticulitis mimic and must be differentiated from neoplastic tuberculosis, chronic appendicitis, actinomycosis, intestinal obstruction, carcinoma, chronic sigmoiditis, sigmoiditis with carcinoma implanted, fecal impaction, encysted foreign bodies, pelvic peritonitis, ovarian tumor, other disease of the adnexa, vesical tumors.

As was natural in the earlier cases with masses involving the sigmoid and upper rectum, occurring, as they usually do, in the socalled cancerous period of life, the diagnosis of malignancy was commonly made. From the knowledge acquired through operation and pathological reports, the clinical diagnosis has become more conservative and more recent cases have been positively diagnosed before operation.

The obscurity which has always existed about this pathological condition is to be expected when we consider that it is a condition likely to be overlooked at necropsy and which may be harmless and symptomless during life.

Other sacs cause but slight disturbance but in a typical case the symptoms and signs of diverticulitis and peridiverticulitis are characteristic. The chief symptom is usually a chronic leftsided obstruction associated with the presence of a tumor in the left iliac fossa in an adult patient.

Abdominal palpation and a bimanual examination will usually reveal the presence of a rather firm, oval, fixed tumor, in the left iliac fossa or lower part of the pelvis, but will not enable one to distinguish between the two conditions. Symptoms of chronic constipation or obstruction over a long period are usually present, and will be in favor of diverticulitis rather than cancer. A careful record of the evening temperature is often of assistance. A raised temperature in cancer is rare, whereas in diverticulitis the temperature is often raised to 99° or 100° in the evening over long periods. A leucocyte count may be of assistance. A positive count being in favor of diverticulitis.

While the history of a slight amount of blood in the stools is very common in carcinoma, it is usually absent in diverticulitis, and this affords a valuable means of distinguishing between the two conditions. It is by no means invariable, however, as blood is occasionally found with diverticulitis, and also the patient may be suffering from piles.

A sigmoidoscopic examination should always be made, and will sometimes afford valuable evidence. Occasionally a definite annular stricture without any break in the lining membrane may be seen with the sigmoidoscope. Such a finding, associated with symptoms of obstruction and a tumor, will be very much in favor of diverticulitis, as against cancer. Usually, however, the colon is so fixed by adhesions that an instrument cannot be passed far enough to actually see the stricture.

Through the sigmoidoscope the mucosa may appear smeared with pus, or an opening may be discovered through which pus is discharged and a probe may be introduced into the sac. Owing to the frequency with which fistulæ connect the bladder and diverticula cystoscopy and examination of the urine for pus are advisable.

It was only with the advance of röntgenology that full recognition of its clinical significance began. It is also important that the surgeon see his fluoroscopic examination personally, because no laboratory report and no röntgenogram can teach him as much as viewing the moving picture with his own eyes. The röntgenograms are later of great value. Owing to their better definitions and their permanence, some features appear in them not visible with the fluoroscope.

Röntgenographic demonstration is often impossible, but when the lumen of the diverticulum communicates with the bowel, the pouch may sometimes stand out clearly from the bowel in röntgenograms taken following the administration of barium enemas or meals. The diverticulum is most clearly defined when the sigmoid is empty. The patient should, therefore, be examined after a barium meal has been passed *per anum*.

As Telling's report shows, a very great number of these masses have been removed and their true pathology not learned until long afterward when they were subjected to a detailed pathological examination; but this exact diagnosis is not vital since removal of the tumor is imperative in every case. The importance of being able to distinguish between these conditions lies in the fact that if diverticulitis is mistaken for cancer, as the tumor is large and fixed by adhesions, hence it usually follows that no operation is performed, and unless, which is rarely the case, complete obstruction is present, it thus may happen that a patient who might have been saved by an operation is not operated upon until it is too late.

Perforation of the diverticulum into the bladder with the subsequent development of a sigmoidovesical fistula is a not uncommon complication; Mummery has seen it three times in his twenty-four cases. Cripps (49) after searching into this subject finds that enterovesical fistulæ are far more commonly the result of inflammatory mischief than due to perforation from cancerous growths. Vesicoenteric fistulæ due to infective or inflammatory factors are usually secondary to abscess formation or reduced resistance of the tissues, which are devoid of drainage or have inadequate drainage, and following the laws of gravity or the lines of least resistance they point through and rupture into the urinary bladder.

Bladder symptoms come on acutely with rigors and the passage of flatus and feces *per urethram*.

Even with all this infective material constantly working into the bladder a serious cystitis does not always develop.

Diffuse inflammatory changes occurred in fifteen of twenty-six patients subjected to cystoscopic examination as reported by George Sutton (50) who concludes that a probable cause for the usual freedom from a diffuse cystitis is that distinct lymph channels are absent within the mucous membrane; that the mucosa is made up of transitional cells of the expansile, protective and nonabsorbable type and that the amount of infective material is being diluted and kept in motion by the ingress and expulsion of the urine, and by muscular activities.

The inflammatory changes in the bladder are somewhat dependent upon, 1, the size of the fistulous opening; 2, the amount and character of the bowel contents and foreign bodies passed into the bladder; 3, urethral obstruction, as in stricture or hypertrophied prostate, and the amount of residual urine, and 4, the type of infective organisms. The urethra may also become clogged by a fecal mass, or other foreign body which may not only cause paroxysms of pain but may help to distend the bladder, especially if the fistulous opening is valve like. In this manner infective agents may be induced into the urethral openings and cause an ascending ureteropyelonephritis.

Vesicosigmoidal fistula may be shown by the cystogram and may be demonstrated by proctoscopic examination. Methylene blue injected into the bladder will pass through the rectum, also, if the solution is injected into the rectum it will pass in the voided urine.

With the assistance of the clinical pathologist a great majority of the cases may be diagnosed during operation, but some require a further pathological investigation in detail. Thus it may be seen that generally speaking, the final diagnosis rests with the pathologist, therefore, the prognosis should be withheld until such examination has been completed.

PROGNOSIS

The prognosis as to life depends principally on malignant or nonmalignant factors, peritonitis, metastatic foci of infection and embolism. Uninflamed pouches may be unfolded or removed with practically no mortality and by prompt recovery. Where peridiverticulitis exists there is some mortality which varies with the extent of the infective process and the response of the patient to medical or surgical treatment. In acute crises complicated by obstruction, peritonitis or abscess the mortality is high. In the three cases reported by Mummery the perforation healed in time after colostomy above the stricture had been performed.

TREATMENT

The treatment of diverticulosis depends on many factors. If the patient is a poor surgical risk it should be palliative. Many patient's lives can be maintained with little or no inconvenience by keeping the feces soft or liquid with laxatives and oils (never purgatives), belladonna and morphine, liquid diet and frequent warm high enemas to empty and cleanse the bowel. Such a course of treatment relieves pain, colic and muscular rigidity and is of much value both as tentative treatment and as preparatory treatment for later surgical procedures. All patients so treated must, however, be carefully watched for stenosis of the bowel or evidence of peritonitis. Later when the condition of the patient allows and circumstances are favorable, surgical intervention is to be planned. The choice of operation will depend on many circumstances which the surgeon must value according to the individual case.

Diverticulitis is a surgical condition since there is no way of destroying the sac except by operation. Numerous small pouches and those of moderate size that have not undergone secondary stanges may be buried by coloplication or ligated, excised, and the stump inverted with a purse string suture or the wound closed, if long, with through and through reinforced by Lembert stitches.

The ideal treatment is to resect the mass and rejoin the ends of the bowel, but this is impractical when diverticula are numerous and widely scattered. Very often this is not possible on account of the dense adhesions to surrounding structures. Nor is it advisable to attempt to separate these adhesions. They are not only very dense, but intersected with septic foci which if disturbed will very probably set up acute peritonitis.

Usually diverticulitis and peridiverticulitis are complicated by infection with abscess formation. If an abscess forms we should not wait for it to rupture spontaneously but should separate its binding adhesions if possible, then incise and drain the cavity.

When there is a fistulous opening between the bowel or bladder and diverticulum, after the sac has been dissected free and the edges cauterized, the aperture is closed by infolding sutures.

In the great majority of cases resection of the affected portion of the colon is not possible, and the alternative lies between shortcircuiting the stricture, or performing a colostomy above it.

If a short circuit is done it is important to be sure that only healthy bowel is used for the anastomosis, and that the tumor itself is not interfered with.

In most cases colostomy is alone possible, and transverse colostomy will have to be performed in order to get well above the diseased area.

Patients, not unnaturally, object to the performance of colostomy, but I would strongly urge that in view of the very serious septic complications which tend to occur, operation should be performed early, and that we should not wait until it becomes urgent.

The result of colostomy in these cases are extraordinarily satisfactory. If the disease has not progressed too far before operation, it becomes completely arrested and the patient regains normal health.

The inflammatory mischief becomes quiescent, and ceases to cause any trouble or produce any symptoms.

When feasible, enteroanastomosis, ileoproctostomy or ileosigmoidostomy or intestinal exclusion is substituted for colostomy to relieve obstruction and procure daily soft evacuation without the nuisance of having feces discharged through the side.

Appendicostomy or cecostomy are useful adjuncts in the surgical treatment of chronic diverticulitis, since they provide for through and through colonic irrigation, which heals inflamed and ulcerated areas, frees the bowel of irritants, and facilitates convalescence from autointoxication.

The author's references will appear in his reprints.

Acute Myeloid Leucemia*

Report of a Case

MARK GORDON, M.D.
Brooklyn, N. Y.

CASE.—A. W., schoolgirl, aged fifteen years, born United States. Chief complaint, precordial pain, shortness of breath, cough, persistent vomiting. Family history negative. Patient had measles and German measles in early childhood. Always suffered from gastrointestinal disturbance, constipation, periodical headaches and vomiting. Menses set in at thirteen years, regular of three days' duration. Last menstruation June 3, 1923.

Patient, a resident of Baltimore, came to Brooklyn on a visit on June 3, 1923. Immediately after her arrival she began to complain of frontal headaches, nausea and vomiting. There was no fever. The patient walked about for a week in this condition, then she began to feel hot, lost her appetite, with general weakness, headache and nausea. The vomiting became more intense. Patient took to bed. There were no abdominal pains nor skin eruption. This condition lasted from June 12th until July 7th. Patient was attended by various physicians for different conditions, among them typhoid fever, pneumonia, influenza and nephritis. No blood count had been made before her admission to the hospital. July 7th she became worse, suffering from intense palpitation, severe precordial pain, dyspnea, cough and incessant vomiting. She was admitted to the hospital July 10th.

On admission the patient looked acutely ill, markedly dyspneic, anemic, no cyanosis, with a peculiar pasty look suggesting nephritis. Temperature 103°, pulse 120, respiration 22. Pupils contracted, reacting sluggishly to light. Ears and nose negative. Teeth in good condition. Tongue flabby, coated, white, furry, moist. Tonsils imbedded and ragged, congested. No lymph glands palpable about the neck, no enlargement of thyroid. Some retraction of the head was evident. Chest presented diminished expansion on inspection with increased vocal fremitus on palpation. Percussion revealed a dull note on both sides. Auscultation elicited some harsh breathing over both lungs and râles here and there, more so in the regions of the axillæ, giving the impression of pulmonary congestion. Heart, diffuse impulse over precordia. Apex in sixth interspace to the left of the nipple line. Area of cardiac dullness increased to left. There was a systolic thrill at apex. Auscultation revealed a mitral systolic murmur at apex, transmitted to the axilla to the left, a diastolic murmur at the apex which was circumscribed. There was accentuation of the second pulmonic. Abdomen, liver palpable four fingers below costal arch, spleen palpable. There was abdominal distention but no fluid could be made out, although there was dullness in the flanks. No masses could be made out. The extremities presented some edema at ankles. Patellar reflexes exaggerated. Positive Babinsky and ankle clonus. No Kernig. A provisional diagnosis of malignant endocarditis with cerebrospinal meningitis was made.

The urine was cloudy, specific gravity 1010, acid, no albumin, no sugar. Microscopically negative. Blood culture negative. Hemoglobin 52 per cent. Blood count showed a leucocytosis of 320,000. The differential was 54 polymorphonuclears, 34 lymphocytes, 12 myelocytes. Three counts were made and the blood picture presented respectively 320,000, 360,000 and 280,000 leucocytes. Myelocytes were from 7 to 12. Fifteen c. c. of spinal fluid was obtained under moderate pressure. Examination showed albumin and a slightly positive Noguchi. Differential count showed thirty-four polymorphonuclears, sixty-four small lymphocytes and four large lymphocytes. There were no bacteria. The diagnosis of acute myeloid leucemia was made.

The disease ran an extremely stormy course. The temperature was 104° and dropped toward the end, which came on the night of July 12, 1923, when the patient died. The case is of interest first, because it brings out the importance of a blood count in every case, particularly in cases of a baffling nature. The second point is its comparative rarity. Cabot speaks of this disease as fully five times as rare as pernicious anemia and about as rare as myxedema. It is more common in males than in females. The disease occurs more often between the thirtieth and fiftieth year. After the sixtieth year it is almost unknown. Before the twentieth year it is extremely uncommon. It is of some interest that when the disease occurs before the twentieth year the female sex predominates.

Gorham in the *Albany Medical Annals* of 1917, speaking of the etiology of this disease, says, "The condition is a fatal disease, of unknown etiology characterized clinically by a short course."

The first case of acute leucemia was described by Von Friedrich in 1857. The patient died two months after the onset of the disease. Epstein in 1889 describes a clinical picture and H. Fraenkel in 1895 called special attention to the pathological changes in the blood. The contributions to the literature on this subject have been voluminous. Many writers maintain that there is no such disease as myeloid leucemia, that all these conditions are lymphemias. The diagnosis of myeloid leucemia, while based largely on the tremendous increase in the number of leucocytes, does not, however, confine itself solely to the quantitive changes in the blood. There are certain periods of remissions when a diagnosis is made on the qualitative changes in the blood. Although all varieties of cells are increased, the most conspicuous cell of all, in these conditions, is the myelocyte. In myeloid leucemia this cell constitutes twenty per cent. Da Costa reports cases in which the myelocytes constituted seven per cent of the cells. In this case there were from seven to twelve per cent. The myelocyte rarely appears in normal blood.

Instruments, Apparatus, and Clinical Notes

A New Instrument for the Use of Heliotherapy in Tuberculosis and Other Affections

J. W. KIME, M.D.

Fort Dodge, Iowa.

As one of the first workers in the field of heliotherapy in tuberculosis, and first of those making use of the condensed rays of sunlight in this disease, I want to refer briefly to the literature of this subject.

Finsen, of Copenhagen, had in the late 90's made use of condensed sun rays in the treatment of lupus. In 1898, I first called attention to the subject of condensed sun rays in the treatment of pulmonary tuberculosis. In the *Journal A. M. A.* for May 12, 1900, and in the NEW YORK MEDICAL JOURNAL for October 13, 1900, and November 1, 1902, I discussed heliotherapy and showed the large sun reflector used for the concentration of sunlight upon the chest in pulmonary tuberculosis and upon the open wounds of surgical tuberculosis. I then published photographs which had been taken through the entire thickness of the thorax. (I know of no other such published photographs.) Reports of cases successfully treated were then, and subsequently, reported.

But the method was new and it has taken many years of patient work to demonstrate the value of a stronger sunlight in this disease. That conservatism which characterizes the medical profession made it necessary to proceed along fixed lines, taking years of time and many types of patients, before the claims of this new form of therapy might be stressed. In consequence, I now find that much of this early work, done more than a quarter of a century ago, has been forgotten while others are now rediscovering, as "original" the things which then were published in these, and other, widely circulated publications.

During these years I have seen light, and especially sunlight, take first rank in the treatment of tuberculosis in all its forms. It is therefore a real pleasure to find these words published by Dr. Samuel H. Watson, of Tucson, Arizona, in *Southwestern Medicine* for January, 1925.

"Following Finsen, current medical literature gives Bernhard of St. Moritz credit of first using sunlight in the treatment of infected wounds and socalled surgical tuberculosis, in 1902, and then Rollier of Leysen, in 1903. Malgat, of Nice, is credited with being the first to use it in pulmonary tuberculosis, in 1904.

"Without wishing to detract from the credit due any of these men, and credit is certainly due all of them, but desiring to see the sequence of events in the history of heliotherapy set forth as they actually occurred, I wish here to record the fact which, apparently, is not known to any of the writers, either native or foreign, who have written on heliotherapy, that the real pioneer, after Finsen, in heliotherapy, for surgical, as well as pulmonary tuberculosis, was an American doctor, living and practising in Fort Dodge, Iowa, Dr. J. W. Kime, by name. Stimulated by Finsen's work on lupus, Dr. Kime was himself treating that disease with the sun in 1897 or 1898. He obtained excellent results, and reasoning that if sunlight was of value in skin tuberculosis, it ought to be valuable in other kinds, he began, in 1900, treating tuberculosis of the lymph glands and lungs. His interest was so intense that he did some research work on the penetration of light rays, and this part of his work has been acknowledged in literature. He also invented a large mirror made of blue glass, which cut out a large part of the heat rays and concentrated the blues and violets. His work so closely following Finsen, who assumed that all the valuable part of the spectrum was at the violet end (we think differently now), it was most reasonable that he should work along this line. Dr. Kime used his mirror to concentrate the rays on the part affected and, in addition, exposed the patient's body to the direct rays of the sun."

John H. Pryor in his article in Billings-Forchheimer's recent work on *Therapeusis of Internal Diseases,* volume 2, makes frequent references to our original work in light therapy. Pottenger, of California, in his *Clinical Tuberculosis,* volume 2, also gives full credit to this work.

So much for the early history and for a stronger and more powerful sunlight in the treatment of tuberculosis.

Sunlight is now everywhere recognized as the very first of all therapeutic remedies for tuberculosis. All writers upon heliotherapy agree that the sun's rays are infinitely to be preferred to those from any artificial source. All other lights are but feeble imitations of sunlight. Upon this point Pryor says, "A great deal has been written about artificial means of light therapy. At best they are but poor substitutes for the sun's energy." Rollier says, "Science has not yet invented an adequate substitute for sunlight."

With these statements we fully agree. We might as well expect a vigorous growth of plant life under the glow of artificial light as to expect any vigorous effect of any kind from such a light. The most that can be said in favor of any artificial light in the treatment of disease is that it is better than no light at all.

Pryor says: "Sunlight was extensively used in the earliest days of medicine. The Egyptians, Persians, Romans and Greeks put it into practical use. It was extensively used by Herodotus and Hippocrates but later fell into disuse until about 1800, and little was done with it until about 1900 when Finsen, Kime, Rollier and others took up the work in a practical way."

Light kills bacteria and concentrated light inhibits the growth of bacteria even in the deep structures of the body. Finsen found that concentrated sunlight killed bacteria fifteen times more rapidly than ordinary sunlight. The bactericidal action of the deep penetrating rays of sunlight is effected by their inflammatory reaction causing increased exudation of serum and the migration of leucocytes, promoting phagocytosis.

FIG. 1.—Reflector of highly polished metal

Upon the skin, sunlight produces an acute erythema with dilatation of the blood and lymph vessels and the exudation of serum and leucocytes. Those who tan best, in whom pigmentation is most marked, most promptly recover.

Upon the circulatory system the effect of the light is marked. The capillaries dilate and we have even found that in open wounds they frequently rupture and blood oozes out upon the surfaces. The violet rays are tonic in their effect, they are soothing to the nervous system, and the temperature declines.

Sunlight is toxic to bacteria and particularly to the tubercle bacillus. Pryor states "that light penetrates the entire thickness of the thorax as shown by Kime, Finsen, Malgat and Kaiser." Pryor also reproduced their work. He concludes that sunlight also penetrates the body to a depth of ten inches, that concentration favors its penetration and that pigmentation favors the absorption of the ultraviolet rays.

He says, "The effects of solar radiation on the general condition of the patient are gratifying to patient and physician alike, the haggard and spiritless appearance giving way to one of cheerfulness and animation. There is a rapid alleviation of pain and usually within two weeks complete disappearance (in joint and bone tuberculosis). Temperature gradually comes down to normal; appetite returns; weight and strength are taken on rapidly and the blood condition improves. Both hemoglobin and red cells increase, leucocytosis becomes reduced and an actual lymphocytosis takes place.

"It has been clearly proved that solar radiations can be successfully applied not only in tuberculosis, but in cases of anemia, rickets, osteomyelitis and nonhealing wounds and in convalescents from wasting and infectious diseases. It cannot be too firmly asserted that heliotherapy, in prevention and curative medicine, must be accepted as one of the most effective agents at the command of the modern therapist and clinician.

"Its specific value in tuberculosis, rickets and the upbuilding of resistance and general physical condition, is known."

We have found in our own work that not only in pulmonary tuberculosis but in bone, joint and glandular tuberculosis, heliotherapy is of the greatest value. In nonhealing wounds repair at once takes place. In lupus it is specific.

A NEW INSTRUMENT

With all the apparatus that has been used in the past for the purpose of concentrating sunlight and removing heat rays, it has been necessary to make use of glass. We have known all the time that the glass cut out the very rays that it was most desirable to use, the ultraviolet rays.

We have just now been able to overcome this difficulty by entirely doing away with glass and making use of highly polished metal reflectors for the concentration of the sunlight, after which it is passed through violet colored screens of celluloid. This permits the passage of the ultraviolet rays.

In this manner the ideal sunlight has been evolved—a powerfully condensed light which uses all the ultraviolet rays, with the elimination of the heat rays—a light exceedingly rich in the short waves, and yet a cold light.

This condenser is five feet in diameter and utilizes all the shorter rays of sunlight—the violet and ultraviolet rays. This apparatus is the most powerful sun therapeutic light in existence and it utilizes those rays which have been demonstrated by all observers to be most efficient in this field of therapy.

METHOD OF USING THE LIGHT

In pulmonary tuberculosis the condensed violet and shorter rays are thrown upon the bare chest of the patient for twenty minutes daily, after he has gradually become accustomed to their use. In addition, the patient is placed upon a cot in the open sunshine with nothing on but gossamer clothing, or no clothing at all, for a period of three hours daily. These applications of sunlight are begun very gradually after the manner of Rollier.

In glandular, joint and surgical tuberculosis the condensed violet rays are turned directly upon the parts affected and into the open wounds of surgical tuberculosis. Response to the treatment in such cases is prompt and effective.

We feel that this form of treatment has been too long neglected and that the use of sunlight, and of the strongly condensed violet and ultraviolet rays, should always be applied to that class of cases to which they are adapted.

The Treatment of Laryngeal Tuberculosis with the Goerz-Wessely Lamp

A Personal Observation and Opinion.

JOSEPH W. MILLER, M.D.

New York

During my sojourn in Vienna I was introduced to a novel method for the treatment of laryngeal tuberculosis. This treatment consists in the application of concentrated artificial light to the upper respiratory passages either directly by means of the Seiffert universal larnygoscope with chest support, or indirectly, by means of the laryngeal mirror.

Heliotherapy for tuberculosis in general and laryngeal tuberculosis in particular is not new.

The healing power of the sun was surely known to ancient civilization but was lost to us during the passing of the ages. It was rejuvenated about thirty years ago when Poncet began to use sunlight in the treatment of tuberculosis. His work made no impression and remained unnoticed. Rollier and Bernhard made extensive investigations and found encouraging results showing that sunlight has an elective therapeutic effect upon all forms of tuberculosis.

Finsen, who did a great deal of work on heliotherapy, found in the carbon arclight an excellent substitute for sunlight which was especially effective in lupus.

But Sorgo was the first to treat tuberculous lesions of the larynx with reflected sunlight and could demonstrate a number of successfully treated cases twenty years ago.

On the other hand, Brünings and Albrecht in experimenting on laryngeal tuberculosis of the rabbit with sunlight and mercury vapor light found after a careful critical study only negative results. Similarly, Blumenthal, who too used sunlight and mercury vapor light on the diseased human larynx by means of laryngofissure, met with the same results.

Notwithstanding the discouraging findings of Brünings, Albrecht and Blumenthal, Wessely of Vienna was inspired with the triumphant Finsen treatment of lupus and skin tuberculosis and especially with the good results obtained with reflected sunlight in many cases of human tuberculosis by Sorgo.

Therefore, in order to investigate critically the value of artificial sunlight in the treatment of tuberculosis of the upper air passages, Wessely began to experiment with that form of light in 1920. He used this method of treatment to the exclusion of all other local or general therapeutic agents.

His experiments and results are the answer to the following questions:—1. "Is local heliotherapy for tuberculosis of the upper air passages in itself of value or not?" 2. "If so, is it possible to construct a method for local heliotherapy which should lend itself for the use of the many." In order to answer these questions, it is necessary to decide what we know definitely about sunlight and its local action upon normal and tuberculously diseased tissue."

Sunlight is not homogeneous light, nor are its rays uniform; instead it is a mixture of rays of different wave lengths which by means of prisms can be reduced according to its respective spectrum.

"The rays appear then, according to their wave lengths, as a colored band arranged in the spectrum. The colors are: Ultrared, red, yellow, green, blue, violet and ultraviolet. It is important to know that rays of different wave lengths act differently upon the skin of the human body.

"Sunlight produces, after prolonged suitable exposure, an immediate hyperemia on the skin as a result of the heat action. This heat action is contributed by the rays of the red end of the spectrum and is, for our purposes, not desired. On the other hand, there appears after a certain latent period, an erythema, which displays a photochemical action of the blue and ultraviolet part of the spectrum. This erythema goes through a characteristic metamorphosis; there appears pigmentation and desquamation.

"The sun's rays can penetrate human tissues and bring about in its depth tissue changes. The power of penetration by the rays of different wave length are not equal. While the heat rays have a considerable power of penetration of a few centimetres, the values for the visible spectrum quickly diminish and amount to in the ultraviolet only fractions of a millimetre; so that even the superficial layer of the epidermis is not pierced. But this in turn effects a fluorescence with the formation of beta rays which penetrate deeper and bring about a chemical reaction in the tissue. This biological effect is proportional to the chemical power and inversely proportional to the capacity of penetration.

"It is known that sunlight has a selective and destructive action upon tuberculous granulation tissue and that this action is mainly due to the influence of the blue end of the spectrum, namely, the ultraviolet.

"Simultaneous with the action it exerts upon tuberculous granulation tissue, the light acts as a powerful stimulant to connective tissue formation; thus forming cicatrization. Besides the local action of the light upon the skin, it exerts a general influence upon respiration, pulse, blood, etc."

The following requirements are necessary for the artificial light to be of value: It must be a chemically active, cool light of a suitable photochemical intensity. It must be so concentrated as to reduce the time of exposure to a minimum and at the same time create an optimal therapeutic effect.

It is needless to state that with any light the action of which would be so weak as to consume an

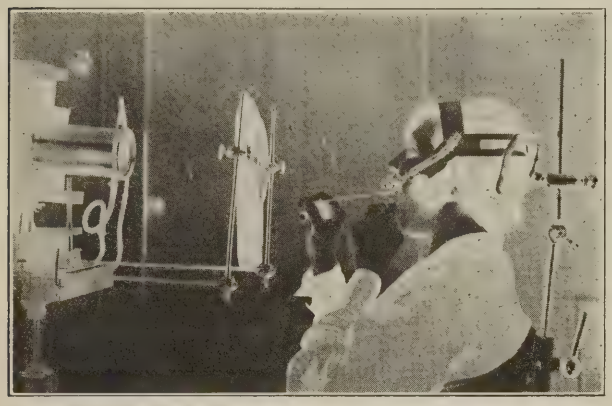

FIG. 1.—Patient looking at her own larynx. Indirect method of irradiation. Patient sits in front of a perforated magnifying mirror and with the laryngeal mirror suspended she can regulate the ray of light directly upon a given lesion.

hour or more for each individual case, it would be impossible to manage such great numbers as are seen to come for treatment at the Hajek clinic. Besides, too prolonged exposure would exhaust the patient and waste valuable time for both physician and patient.

Since it is known empirically and theoretically that the maximum amount of light energy causing erythema and pigmentation is due to the rays having a wave length of 300 mm. and that these rays are located at the outer or blue end of the spectrum, i. e., the ultraviolet end, Wessely began to experiment with these rays to the exclusion of all others.

To imitate the blue end of the sun spectrum was the first aim, the employment of a tremendous light energy was the second, and an apparatus which should allow the light energy to strike unaltered at a desired spot was the third.

The carbon arclight yields rays closely imitating sunlight but the ordinary arclight in itself is not the best imitation of sunlight. But with the addition of a certain substance—metallic salt—to the carbon bars, the blue end of the spectrum becomes complete. (Such impregnated carbon bars are now manufactured by the optical concern C. P. Goertz Co. of Vienna.) By utilizing these special carbons, the arclight produces rays having a wave length of 290 mm. embracing the entire ultraviolet of high altitude sun at zenith.

In order to destroy tuberculous tissue, i. e., to bring about its degeneration, only powerful and concentrated light is necessary. By a special designed Goerz system the superficial brightness is doubled, which also shortens the time of exposure to irradiation.

Briefly, the Wessely lamp is an arclight which burns with specially constructed and impregnated carbon bars according to the Goerz system, by which the greatest concentration of rays is thrown to one side and made to converge into a cone through the medium of a quartz optic. The heat rays are absorbed by a water jacket connected with the quartz optic. In other words, this machine is a carbon arclight, watercooled, quartz lamp.

With this lamp only one patient at a time can be treated. The average time of exposure is eight minutes, given at first every other day and later at longer intervals. About twenty patients are treated during the forenoon. Those in good general condition, or otherwise are favorable subjects, are irradiated directly by means of the Seiffert universal direct laryngoscope with chest support. Patients so treated have the benefit of the ultraviolet rays striking the lesion directly, shortening the period of treatment considerably. Frail individuals or those with advanced pulmonary lesions or those intolerant and too sensitive for the direct method, are treated indirectly in the sitting posture by means of an all metal laryngeal mirror which is held suspended by a special contrivance attached to the teeth. These steel mirrors are utilized because they reflect at least forty-four per cent. of the valuable therapeutic rays into the larynx; while the ordinary glass mirrors absorb these rays, reflecting only about nine per cent. It goes without saying that this method is not as good as the direct method, although more comfortable. The patient sits in front of a large mirror which is centrally perforated like a head mirror and can see his own larynx. In this manner he is able to regulate the laryngeal mirror himself whenever the rays do not strike a desired area. Cocaine hydrochloride ten per cent. to which a few drops of adrenalin chloride are added is used to swab once or twice the soft palate, root of tongue, posterior pharynx wall and the interior of the larynx whether the direct or indirect methods are used.

The period of treatment varies from a few weeks to one and one half years. At the end of treatment, the patients are advised to call once a month for observation. Through the courtesy and kindness of Professor Hajek and Dr. Wessely I was given

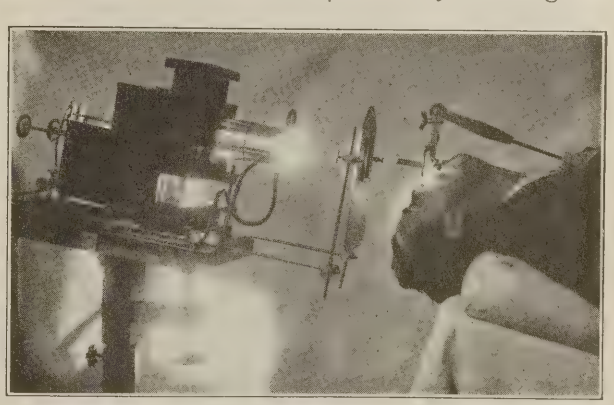

FIG. 2.—Direct method of irradiation. Patient suspended by means of the Seiffert direct universal laryngoscope, rays striking the lesion directly.

free access to the phototherapy department and the privilege to examine patients at random. Superficial tuberculous ulcers heal under this form of treatment rapidly leaving at first a small depression which soon fills out to an even surface. Granulations become smaller and shallower and one can distinctly differentiate the irradiated area from the non irradiated one. Only the irradiated ulcer heals.

Those neighboring in juxtaposition and not exposed to the rays are not so influenced. Massive infiltrations of the posterior larynx wall under the influence of the rays change their shape and become smaller. Finally, there remains a pale transverse elevation which on phonation is thrown into several folds.

Dysphagia, when due to superficial ulcerations, disappears in many cases, following only two or three exposures; when no change even in the appearance of the lesion is yet noticeable. Of course, there are cases with extensive tuberculous destruction of the upper air passages—destruction beyond repair—where the light treatment gives no analgesia nor any other favorable symptomatic results. These are patients with fulminating tuberculous lesions of the lung whose resistance has sunk so low that nothing can stimulate their recuperative powers to tissue repair. Recurrences on the same or other parts of the upper air passages are not uncommon while there is an active lesion in the lung.

At any rate, this form of treatment gives results which have hitherto not been attained by any other form of treatment. The patient becomes more cheerful and his confidence in the hope of getting well is strengthened. The ability to swallow food and drink comfortably gives these unfortunate persons a chance to fight their primary pulmonary affection.

Ambulatory and afebrile patients and those with no progressive lesions are best suited for light treatment. Before treatment is begun the patient's condition is determined carefully. A thorough chest examination both physical and röntgenological is made and the blood examined to determine the relative rapidity of the sinking of the erythrocytes.

Dr. Wessely told me that he observed in several cases the pathological condition of the larynx clear up entirely under treatment, while the patient's pulmonary affection either remained the same, or else became progressively worse; thus having no influence at all on the pulmonary condition.

Without becoming at all overenthusiastic, it is my profound belief as it is the belief of those who had an opportunity to study with Dr. Wessely, that this form of treatment heals, if not actually cures, laryngeal tuberculosis.

These encouraging results achieved by Wessely in Vienna prompted me to import this lamp to the States. Great difficulty was encountered in obtaining the first few cases; as most of these unfortunates are confined to various hospitals and sanatoria. While some of the hospitals offered me the opportunity to treat such cases with the irradiation lamp, it was under condition that I bring the lamp to the respective institutions. This I found impossible, due to the fact that the lamp is massive, unportable and needs a specially constructed rheostat.

Notwithstanding these difficulties, I succeeded in getting three ambulatory cases of laryngeal tuberculosis up to November 23, 1925. Two of these cases are of the advanced type and reveal extensive infiltration of the aryepiglottic folds, ventricular bands, interarytenoid space and almost complete destruction of both cords. One of these has in addition marked tumefaction of the epiglottis and ulceration of the interarytenoid space. The third patient shows extensive swelling of the right aryfold, interarytenoid space and right ventricular band so much so that the right cord is not at all visible. The left side of the larynx is only slightly involved.

The condition of all of these patients was diagnosed tuberculous cases; as all of them have pulmonary tuberculosis, all had frequent positive sputum examinations and were confined for various periods in hospitals and sanatoria devoted to the treatment of tuberculosis.

It is too early, as yet, to give a detailed report on the outcome of these cases, as the first patient was under my care for only three weeks at the time this paper was written. A full report on the results obtained with this mode of treatment will follow in a later communication. Suffice it to state that the first two patients treated have improved considerably. Their pain and laryngeal irritation have subsided entirely and it is their enthusiasm and satisfaction, more than what I have seen in Vienna, which prompted me to write this paper.

Cholecystography in Its Application to the Diagnosis of Cholecystic Disease.—More than eleven hundred patients were examined at the Mayo Clinic by cholecystography. The sodium salt of tetrabromphenolphthalein and that of tetraiodophenolphthalein were used, and each salt was administered orally and intravenously. In a comparison of the methods, Russell D. Carman (*Lancet,* July 11, 1925) states that the intravenous administration of the dye offers advantage in superior control of the patient, certainty that the specified dose of the drug has been given, and emphasis of the shadow obtained. Its disadvantages are the requirement of a punctilious technic and the hazard of local or systemic reactions. With identical technics the bromine salt given intravenously seems to be more provocative of systemic reactions than the iodine salt, if the latter is pure.

Simplicity and freedom from grave reactions are the principal advantages of oral administration. With either salt, nausea and purgation ensue occasionally. The iodine combination, even when pure, seems to produce these discomforts more often than the bromine. Vomiting after taking either drug, unless early, has apparently had no material effect on the shadow.

Dye in the intestinal contents produces shadows which may be a little confusing and might possibly conceal the shadow of the gallbladder, but such circumstances are infrequent. Lack of certainty that all of the drug has been taken as directed is another minor objection. The question may also arise as to whether defective absorption from the intestine may not be the cause of abnormal findings. However, all these objections and doubts seem to have little basis, for in this series the diagnostic results from all methods were about equal.

From these considerations it will be apparent that the author's present preference is for the oral use of the bromine salt as a routine and the iodine intravenously to check doubtful cases.

Affections of the Respiratory System in Relation to Joint Tuberculosis*

HENRY KELLER, M.D.

New York

PRIMARY FOCUS OF INFECTION IN JOINT TUBERCULOSIS

It is the consensus of opinion of practically all observers that joint and bone tuberculosis is caused by a focus located elsewhere in the body and only through one cause or another finds the vicinity of the joint the proper medium for invasion and development.

MacCallum, in discussing tuberculosis of bones and joints, agrees with that dictum in the following statement: "In all instances except in those in which the skeletal structures are encroached upon by tuberculous processes arising in adjacent tissues the bacilli must be brought to them by the blood stream, and it is practically certain that such bacilli come from some primary lesion which may be so small as to be overlooked or may be healed when the osseous lesions have developed." (1.)

Jones and Lovett in discussing prophylaxis in bone tuberculosis in children remark that, "no question is more important in connection with bone tuberculosis in children than a consideration of how it may be prevented or minimized. It must be remembered in this connection, the authors continue, that bone tuberculosis in the joints is regarded as a secondary manifestation, and generally secondary to infection of the lymphatic glands of the abdomen and mediastinum." (2.)

AGE AT WHICH JOINT TUBERCULOSIS IS MOST PREVALENT

Though one must bear in mind that adults are not immune to tuberculous involvement of joints, and that even old age is not a barrier to the infection, the first decade of life seems to be the most susceptible age for the invasion of tuberculosis in joints, and bones in the vicinity of the joints. Thus, of 1,259 cases of Pott's disease of the spine reported by Whitman, 1,075 or eighty-five per cent. of the patients were in the first decade; fifty per cent. were from three to five years, inclusive, at the inception of the disease.

In one thousand cases of hip tuberculosis 87.2 per cent. were in the first decade, and 45.2 per cent. were from three to five years of age, inclusive.

In one thousand cases of knee joint tuberculosis, reported by the same author, seventy-five per cent. were in the first decade, and forty per cent. were from three to five years, inclusive. (3.)

Alfer's table of statistics, from Trendelenburg's clinic at Bonn, show the relative frequency of tuberculosis at the different ages as follows:

Of a total of 966 cases including diseases of the region of the vertebræ, hip, knee, ankle, shoulder, elbow and wrist, the ages of the patients were as follows:

0— 5	=	207	40—45	=	31
5—10	=	195	45—50	=	18
10—15	=	148	50—55	=	19
15—20	=	139	55—60	=	15
20—25	=	60	60—65	=	13
25—30	=	47	65—70	=	3
35—40	=	29			

It is also important to bear in mind that according to the present day teaching even tuberculosis which shows its full manifestations in later age owes its origin to childhood. Metcalf, in his book dealing with tuberculosis of the lymphatic system, puts it very clearly: "At the present time there is a strong tendency to believe that nearly all cases of tuberculosis have had their origin in early childhood. Proofs for this supposition are not lacking. The cutaneous tuberculin reaction, so rare during the first few months of life, increases in frequency with every year, to reach its height between the ages of ten and fifteen years." (4.)

It must, however, be clear in our minds that not all who react positively to tuberculin or von Pirquet tests are suffering from tuberculous disease. For even in children there must be a differentiation made between tuberculous infection and tuberculous disease.

"Taking into consideration," says Metcalf, "the large number of children who react positively to the tuberculin test, Morse's distinction between tuberculous infection and tuberculous disease seems rather well taken. He defines infection as the state of being infected, and disease as an alteration in the state of the body, or of some of its organs, interrupting or

*From University and Bellevue Clinic in collaboration with Dr. Reginald H. Sayre, Dr. Leon Theodore Le Wald, Dr. Arthur J. Huey, Dr. David H. Barash, and Dr. Philip Wettervik. Paper read before Riverside Medical Association of New York City, April 21, 1925.

disturbing the performance of the vital functions and causing symptoms of some sort. A comparatively small proportion of the children showing a positive von Pirquet test have tuberculous disease; they are, however, infected. It is the reaction of the tissues to the infection that constitutes the disease tuberculosis; also known as clinical tuberculosis."

LOCATION OF INFECTION OF TUBERCULOSIS IN CHILDREN

As we have stated before, tuberculous infection in childhood is responsible for the great majority of tuberculosis in all ages, it is therefore important that we attempt to elucidate the location of tuberculous infection in childhood.

"Postmortem findings," says Metcalf, "indicate that the most common site of tuberculous lesions in early infancy is in the bronchial and mesenteric glands. In early childhood the cervical glands run a close third. In Medin's series of 632 tuberculous infants under one year the localization was as follows:

In lungs only	78 cases
In bronchial glands	17 cases
In both lungs and bronchial glands without involvement of digestive tract	194 cases
In digestive and mesenteric glands	6 cases
In portal glands and liver only	1 case
In respiratory and digestive tract	313 cases
Location not given	7 cases

It is worth while to emphasize the salient points of Medin's statistics that, whereas mesenteric glands alone were involved in six cases only, the bronchial glands and the lungs were involved in 194 cases. On the other hand, in 313 cases both the respiratory and the mesenteric regions were involved.

The statistics of Wollstein and Bartlett of 178 autopsies on tuberculous children under five years of age are even more eloquent, thus:

In lungs	164
Bronchial glands	169
Mesenteric glands	139
Mesenteric glands alone without bronchial	9

THE TONSIL AS THE AVENUE OF INFECTION

Due to their situation any bacilli entering the mouth and being swallowed pass over the surface, and may thus find lodgment in the crypts of the tonsils. Mouth breathing caused by nasal obstruction or other causes will permit the dust to enter through the mouth, reaching the tonsils which act as the first line of defense.

Ravenel, in speaking of various avenues of infection as etiological factors in tuberculosis, says of the tonsils that, "they may be the seat of primary tuberculosis, and often show scars and other changes attributable to tuberculosis." Lathan, quoted by Ravenel, examined the tonsils of twenty-five children autopsied, ranging in age between three months and thirteen years, and he found seven cases whose tonsils were tuberculous. (5.)

Metcalf, in speaking of the frequency of tonsillar tuberculosis, calls attention to the fact that even in cases when no tuberculous symptoms are present examination of the tonsils reveals the presence of tuberculosis in from four to six per cent.

It is also worth while calling attention to another important statement made by the same author with reference to tonsillar affection, namely, that the small and buried sclerosed tonsils are often a greater menace than the tonsils of normal size. "The small sclerosed tonsil may increase the facility of infection, because of its crypts having wider openings on the buccal surface than normal; also because of atrophy of the lymphatic tissue."

In our series of cases studied at the University clinic, the examination of the tonsils in the forty cases treated for joint tuberculosis showed that thirty-two of the forty had tonsillar infection.[1] Five of the thirty-two patients had their tonsils removed prior to their coming to our clinic, and twenty-seven were still in possession of them. Some were of the sclerosed type of which Metcalf speaks, while others were of the hypertrophic type—distributed as to age as follows:

to 5 years	= 6	20 to 30 years	= 2
5 to 10 "	= 6	30 to 40 "	= 6
10 to 20 "	= 6	40 "	= 1

ASSOCIATION OF LUNG AND JOINT TUBERCULOSIS

Jacquemin in studying cases of tuberculosis of both lungs and joints, elaborates upon the prognostic importance of such combination. He discovered that the prognosis depended on which process began first, as the second process acts like a derivation or a fixation abcess, diverting the disease to this second point. When this second process occurs in the lung, these vital organs soon become compromised, but when the process of derivation is on a limb it does comparatively little harm, and this second process should be encouraged rather than suppressed. Hence the prognosis is comparatively favorable when the bone or joint process has developed secondarily to the pulmonary process.

The author also cites a number of instances of each type, and also cites some cases to show the disastrous results when a secondary bone or joint process was operated on and cured, thus, depriving the primary lung process of this outlet. On the other hand, benefit resulted when a primary bone or joint process was operated on and cured, the necessity for the lungs sacrificing itself thus being done away with. (6.)

MacKinnon has made a study of thirty cases of adults suffering from bone and joint tuberculosis, at the Galloway-Gibson clinic, and he comes to the conclusion that tuberculosis in adults is a general disease in which lesions of the lung are almost always present. He further remarks that bone and joint tuberculosis is not a frequent complication of pulmonary tuberculosis. A large percentage of adults suffering from bone and joint tuberculosis are definitely ill with pulmonary tuberculosis, or are in danger of becoming so, and this fact must be borne in mind in deciding upon the treatment of each patient. (7.)

The observation and conclusions of MacKinnon are contrary to the findings of all other observers who are in accord with the statement of Marsh that patients suffering from tuberculous disease of the joints are little liable to phthisis. (8).

Although in adults the complication is somewhat more frequent it does not warrant such sweeping assertion as that made by MacKinnon, that all adult cases of bone and joint tuberculosis have pulmonary involvement.

[1]Five specimens submitted to Dr. J. A. Fraser for examination showed the infection to be of a nontuberculous nature.

In my own series of forty-six cases of joint tuberculosis reported in this communication, forty of which underwent a painstaking physical examination from a medical and orthopedic point of view, as well as backed by a thorough röntgenological examination, the findings were as follows:

Number of cases of joint tuberculosis treated at University and Bellevue clinic during early part of 1925=forty-six. Male=22. Female=24.

19 months to 5 years	13	Male 7, Female 6
5 years to 10 years	11	Male 5, Female 6
10 years to 15 years	5	Male 4, Female 1
15 years to 20 years	5	Male 2, Female 3
20 years to 30 years	6	Male 2, Female 4
30 years to 45 years	6	Male 2, Female 4

	Parts Involved	
19 months to 5 years	Spine 6	Male 2, Female 4
	Hip 3	Male 3, Female 0
	Knee 4	Male 1, Female 3
5 years to 10 years	Spine 3	Male 2, Female 1
	Hip 3	Male 2, Female 1
	Knee 4	Male 1, Female 3
	Ankle 1	Male 0, Female 1
10 years to 15 years	Spine 3	Male 3, Female 0
	Hip 1	Male 1, Female 0
	Knee 1	Male 0, Female 1
15 years to 20 years	Spine 4	Male 1, Female 3
	Hip 1	Male 1, Female 0
20 years to 30 years	Spine 4	Male 2, Female 2
	Hip 2	Male 2, Female 0
30 years to 45 years	Spine 4	Male 2, Female 2
	Hip 1	Male 0, Female 1
	Sternum 1	Male 0, Female 1

In the entire series we had only four positive cases of pulmonary involvement.

Ages of those involved	
20 to 30	3
45	1
Total	4

Three of the four patients with the pulmonary involvement had the lung process prior to the joint involvement.

These above statistics show that pulmonary infection following bone and joint tuberculosis is small in number indeed.

On the other hand, it is interesting to observe that the x rays of the chests of the forty cases carefully studied showed the presence of enlarged mediastinal and parabronchial glands in twenty-seven cases. In some of the patients the glands in this region were so abundant and so conspicuous in size that one could not but feel that these glands played a very important part in the present condition of the involved joint and that, in determining the mode of treatment to be instituted the presence of these enlarged lymph nodes should not be lost sight of.

Even in the youngest cases of our series were those large bronchial glands present to such an extent that their existence could not be ignored.

It seems, therefore, reasonable to assume that the bronchial lymph glands found in such abundance in these cases are probably the source of supply of the systemic infection. Ordinarily the lymphatic glands, as pointed out by Metcalf, are better fitted to combat infection in childhood than in adults, because of the greater abundance of lymphoid cells and the lesser amount of fibrous tissue. The lymph glands form, on account of their capsules, organs which are entirely enclosed except for the afferent and efferent vessels. Toxin produced by retained bacteria will therefore not diffuse themselves so readily into surrounding tissues. The concentration of the toxin hinders the growth of the bacteria and causes a reaction of the tissues, coagulation necrosis resulting, which together with the stasis and thrombosis of the lymph and bloodvessels aids in the prevention of further disposal of the bacteria.

The presence of such necrosed bodies with filled emboli are a menace and an uncertainty and may at any time, provided the protective means usually at hand are somewhat diminished, cause a new breaking down of the lymph nodes, and thus, supply fuel for a fresh outbreak involving another joint, or causing at times a recrudescence of the already subdued old inflamed joint. (9.)

JOINT TUBERCULOSIS OF THE UPPER EXTREMITY IN RELATION TO GLANDULAR AFFECTIONS

It is the consensus of opinion of all observers that tuberculous involvement of the upper extremity is comparatively infrequent, and secondly, that whereas in joint tuberculosis involving the trunk and lower extremities the first decade of life is the age in which the involvement is most prevalent, and the ages between three and five yield the greatest number—in the upper extremity, on the other hand, especially in the shoulder region, the second decade together with the third yield the greatest number.

Thus, Alfer reports 966 cases of tuberculosis of joints from Trendelenberg's clinic at Bonn as follows:

239	vertebræ
241	hip
281	knee
43	ankle
28	shoulder
114	elbow
20	wrist

CITED BY WHITMAN (3)

Jones and Lovett in speaking of tuberculosis of the shoulder remark that the disease is uncommon in this location in childhood, and in both children and adults, tuberculosis of the upper extremity is much less common than that of the lower. To prove their contention they cite statistics of 7,474 cases of tuberculosis of spine and joints treated at the Boston Children's Hospital where only seventeen involvements of the shoulder joints were noted. (10.)

Whitman gives a summary of statistics of 3,561 cases of bone and joint tuberculosis of which

		Per Cent	
1432	or	40.2	trunk
2018	"	56.6	lower extremity
111	"	3.1	upper extremity

That the upper extremity, especially the shoulder joint, is exposed to trauma is a fact well known, and

FIG. 1.—Pott's disease, middorsal, of three years' duration, in a child of five. Note enlarged glands in pulmonary and cervical regions.

FIG. 2.—Involvement of eighth and ninth dorsal vertebræ with abscess formation in a patient thirty-two years old.

can not be given as a reason for the small number of involvements of that region. C. R. Scott, in his radiological analysis of 1,226 fractures as to locations found that, whereas the vertebræ represented 2.11 per cent., the humerus represented 4.89 per cent., the clavicle 3.26 per cent. and scapula 1.38 per cent. Hence the strain at or about the shoulder region resulting in fracture amounted to 9.53 per cent. (11.)

In this connection it is also interesting to observe that the shoulder joint as represented by the head of the humerus is more active and participates in the growth of the upper extremity to a greater extent than do the epiphyses of the lower part of the humerus and upper part of the radius and ulna—all the three constituting the elbow joint.

It is important to note, says Kirmisson, that the different epiphyses do not all possess the same physiological value. Of the two epiphyseal cartilages in the long bone, one always plays a much greater part than the other in the development of the length of the bone. This epiphysis is termed the fertile cartilage. The nature of these fertile cartilages varies in the superior and inferior extremities. In the upper extremity the fertile epiphyseal cartilages are the superior extremity of the humerus, and in the inferior extremities of the ulna and radius. In the lower limb, on the contrary, the epiphyseal cartilages of the lower end of the femur and of the upper end of the tibia cause increase in the length of the limb. (12.)

Jones and Lovett in giving the reasons for joint tuberculosis attacking children state that "One of the chief reasons that this (joint tuberculosis) occurs so frequently in early middle childhood is, that this is the active period of epiphyseal growth when the neighborhood of the epiphysis is largely supplied by blood."

We should, therefore, expect that the more active epiphyses would be the ones to suffer most frequently. Therefore, the small number of shoulder joint involvements become conspicuous by proving the exception to the general rule.

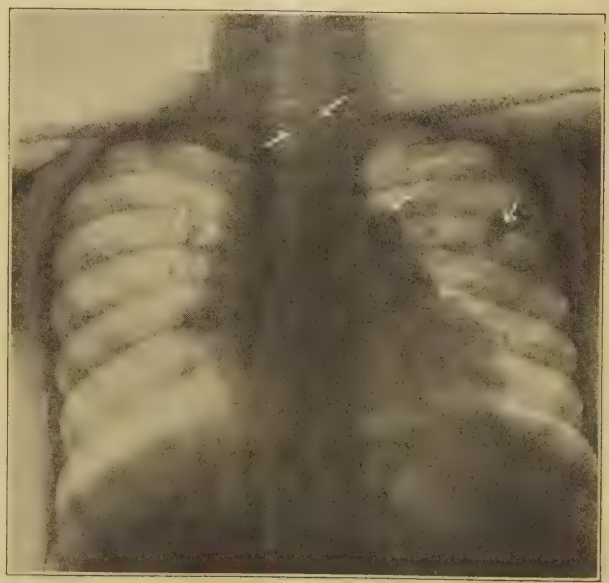

FIG. 3.—Pott's disease of cervical region in a child five years old. Note abundance of enlarged glands.

It is also interesting to bear in mind that in spinal tuberculosis the cervical region yields the smallest number, thus, of 1,355 cases of Pott's disease reported by Whitman as to region:

100	cervical
854	dorsal
317	lumbar

As a result of his statistical studies Whitman concludes that the dorso lumbar section of the spine is most often affected, while cervical disease is comparatively infrequent.

Tubby quotes Redard

who observed one hundred cases at the Dispensaire Furtado-Heine, giving the following statistics as to location: Six cervical, five cervicodorsal, sixty-two in the dorsal, five dorsolumbar, twenty in the lumbar, and two in the lumbosacral region. He further quotes Parker that out of 149 cases of Pott's only nine were in the region of the cervical. (13.)

Looking about for a reason for the small number of cervical Pott's disease and also the infrequency of shoulder tuberculosis, especially in early childhood, one can not help but wonder at the close connection between the above figures and the statistics of cervical adenitis and its age incidence.

Thus, Fischer, who has collected 1,484 cases of tuberculous cervical adenitis is quoted by Metcalf to have found as follows:

Age Years	*No. of cases*	*per cent*
1 - 5	59	3.97
6 - 10	120	8.08
11 - 15	233	15.7
16 - 20	469	31.6
21 - 25	282	19.
26 - 30	130	8.67
31 - 35	63	7.25
36 - 40	43	2.89
41 - 45	25	1.68
46 - 55	29	1.95
56 - 65	18	1.21

Metcalf, after citing his own 270 cases which practically bear out the findings of Fischer, concludes as follows: "These figures show that the frequency of cervical glandular tuberculosis is most marked in the second decade. This undoubtedly is dependent upon the concomitant frequency of decayed teeth and diseased tonsils during the same period.

"How intimate the relationship is between the tuberculous affections of the shoulder and cervical adenitis I am not in a position to say, but that there seems to be a peculiar coincidence in its statistical similarity (as well as in cervical tuberculosis) no one can gainsay.

"In concluding our preliminary report we feel justified in emphasizing that, in treating joint tuberculosis one is treating the result of a primary infection found elsewhere in the majority of cases. In order to eradicate the cause of the joint manifestation one must therefore try to ferret out the underlying primary causative factor. The tonsils and adenoids, if enlarged, must receive adequate therapeutic consideration. Enlarged lymph nodes should be dealt with by conservative methods, namely, by sunlight in the summer, and assisted by exposure to ultraviolet rays in the winter, the placing of the patient in a proper and healthy environment and proper diet.

"In view of the fact that so many of the patients afflicted with joint tuberculosis have large lymph nodes in their chest which latter may be a potential menace to the future wellbeing of the patient, especially so in the young, we would advocate the administration of properly filtered x rays to the chest, in order to cause a shrinkage of those enlarged bronchial and tracheal glands. Metcalf, in speaking of x ray therapy in glandular tuberculosis emphasizes its selective action. "The favorable influence of röntgen therapy in tuberculosis of the lymphatic glands is due largely to this selective action of the rays upon the lymphoid tissue of the glands, since the tissue is in a state of chronic inflammation and attended by proliferative changes. These cells are destroyed and replaced by fibrous tissue cells, as can be demonstrated by operation, or by miscroscopical examination. The lymphatic channels also become converted into fibrous tissue, thus eliminating the possibility of further spread of the disease and isolating it in the lymph nodes, where it is finally overcome.

"This destructive effect upon the lymphatic element, as well as upon all cells which have a marked faculty of proliferation, is the most pronounced action observed. The growth of connective tissue cells is stimulated and cicatrization follows."

Of course, it is self evident that such administration should, and must, be given by an expert who knows how to regulate the dose, the distance and the time of interval for exposure, and also how to measure the rays.

CONCLUSIONS

1. Bone and joint tuberculosis has its origin, in the majority of cases, elsewhere in the system. The latter acting as a primary focus supplying the fuel whenever the susceptibility of the articular region is present.

2. The presence of the abundant and enlarged lymph nodes in the chest, in the region of the pulmonary hilus, as well as in the mediastinal region, seems to bear out the contention of many observers that in this region the presence of the primary focus is most often found.

3. Röentgen examination of chest should always accompany the röntgenological examination of the joints in tuberculous affections of the latter region.

4. Therapeutic measures directed towards curing the diseased joints alone are only part of the treatment.

5. The method of therapeutic approach which aims at the eradication of the original focus of infection is the most plausible method to be pursued.

6. Radiation of the chest should be tried in those cases where enlarged lymph nodes in the chest are present accompanying the joint disease. Such procedure seems to be a valuable adjunct to the protective, as well as other therapeutic measures, which are ordinarily applied in caring for those afflicted with joint tuberculosis.

Especial appreciation is extended to Dr. Wm. J. Pulley, medical superintendent of the University clinic for his courteous cooperation, also to Miss Kate Keenly, clinical clerk of the Orthopedic Department.

Acute Disseminated Bronchopneumonia Simulating Acute Miliary Tuberculosis*

JULES BLECHSCHMIDT, M.D., H. HARRIS PERLMAN, M.D., P.D., and LEON S. COHEN, M.D.
Philadelphia, Pa.

Acute disseminated bronchopneumonia is not commonly encountered in children. It is more frequently seen during the first two years of life, and is characterized by a widespread infection of the smaller bronchioles of both lungs.

The symptoms and physical signs resemble acute miliary tuberculosis so closely that even with the finer technic and modern means of diagnosis, one is apt to confuse the condition with the socalled galloping consumption and yield to an erroneous inference.

CASE REPORT

The case under our observation occurred in a boy nine and one half years.

The chief complaints were a harsh unproductive cough and irregular fever. Father, mother, one brother, one sister were all living and in good health. There was no history of tuberculosis in the immediate family.

Patient was a full term normal birth. Normal dentition. Breast feeding for one year, then mixed foods were given. Two attacks of measles, according to mother's statement, at ages of three months and three years respectively. Good recovery each time. Pertussis at eleven months with a complete recovery. No pneumonia. Tonsillectomy and adenoidectomy in 1921, prior to which time patient experienced frequent and repeated colds. Good recovery following operation.

The present illness began September 23, 1924, with continuous vomiting, irregular fever, chills, headache and a dry unproductive cough. The mother believed these were due to a beginning cold and put the child to bed. The following day the symptoms disappeared. The boy felt better and resumed his outdoor life. Nine days later projectile vomiting occurred after his breakfast. A dose of castor oil followed by free catharsis produced a feeling of well being. The next two days the child felt well. October 6th while playing, he experienced a severe frontal headache. Severe cough accompanied by sharp agonizing pain in the upper abdomen. Fever with rigors and chills were present. The patient refused food and marked constipation occurred. These symptoms increased in intensity with profuse perspiration over the entire body. Consciousness remained clear until thirteenth day of illness. At that time the symptoms and physical signs were most pronounced. Admission to the Jefferson Hospital followed on October 14th, exactly two weeks after the onset of the illness.

Physical signs.—Upon admission to the hospital the signs were identical with those seen at patient's home, except that they were more marked and intense than previously. Inspection revealed a well nourished boy fairly comfortable but dyspneic. Cyanosis was extreme. Head and eyes were negative. The cheeks were suffused and remarkably bluish. Lips were colored—almost blue. Tongue coated. Pharynx reddish, otherwise normal. There was slight pulsation in both carotids. Anterior cervical chain of lymph nodes on both sides were moderately enlarged.

Expansion of the lungs was about equal but limited on both sides. The respiratory movements were mostly abdominal.

Palpation confirmed inspection. There was no apparent increase in vocal frenitus.

Percussion revealed small areas of tympany and normal lung resonance irregularly scattered throughout the chest anteriorly and posteriorly.

On auscultation the breath sounds were harsh and loud of the bronchovesicular variety. Inspiration was louder and longer than expiration during the latter course of the disease. Râles both coarse and moist were present from the very start. The râles covered the entire pulmonary area and were heard both on inspiration and expiration. We were impressed with the widespread region which the infecton involved.

The heart action was very rapid. Heart sounds were of good character and quality until the thirteenth day of illness, when the heart showed evidence of falling behind in its work. At that time heroic treatment was freely employed.

The abdomen showed slight degrees of tenderness over the upper half. Liver enlarged two fingers' breadth below the right costal margin. Spleen was easily palpable. Extremities were negative. Kernig's sign was absent. The reflexes were slightly increased.

LABORATORY TESTS

1. *Blood.* Hemoglobin 85 per cent. — white blood cells 21,600, polymorphonuclears 79 per cent., small mononuclears 16 per cent., large mononuclears 3 per cent., eosinophiles none, transitionals 2 per cent., other cells none. White blood counts: Oct. 15th, 31,800; Oct. 17th, 20,400; Oct. 18th, 22,500.

2. *Sputum.* October 17th, gram positive, diplococci, micrococcus catarrhalis, staphylococcus, no tubercle bacilli found. October 18th-19th—No tubercle bacilli.

3. *Feces.* Color greenish brown—positive for blood, no parasites or ova, bile positive.

4. *Urine analysis.*—Four examinations, October 14th, 16th, 17th and 22nd, showed nothing abnormal.

5. *Blood* for Widal reactions October 18th—negative.

X ray examinations.—In presenting for your consideration the röntgenological aspect of certain phases of lung pathological changes, we would remind you that the röntgenologist's task is to interpret only that which he observes on the skiagraphs. We deal in variable densities and the shadows cast by normal, abnormal, or diseased tissues, are of vary-

*Read before the Philadelphia Pediatric Society, May 12, 1925.

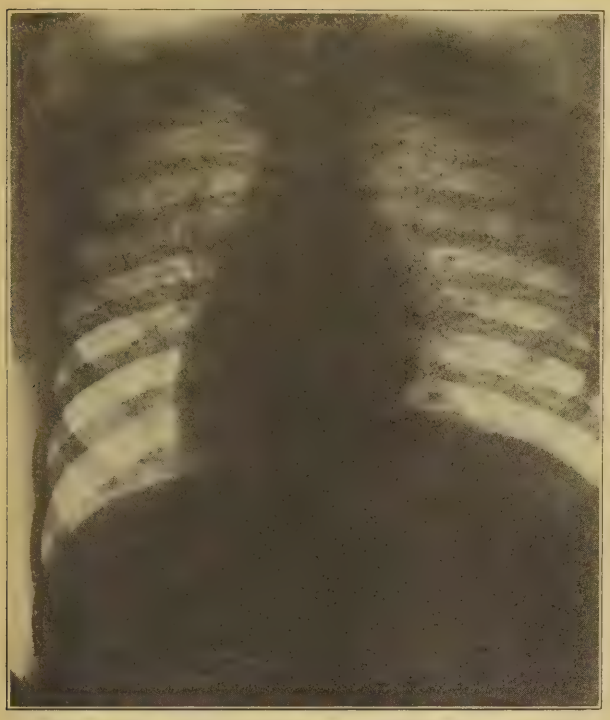

FIG. 1.—Case I. M. G. Disseminated bronchopneumonia.

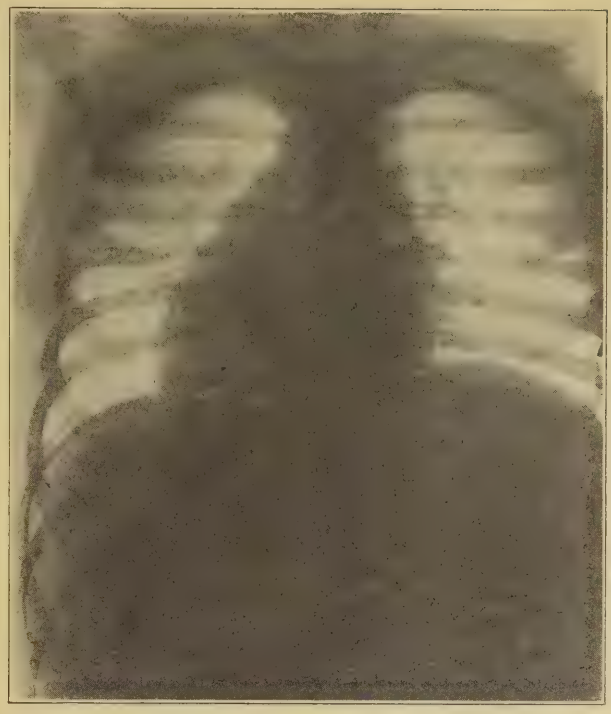

FIG. 3.—Case I. M. G. Showing the lungs fairly well cleared.

ing density. This interpretation must be made in pathological terms so as to correlate it with the clinical entity in so far as it is possible. In future years, there is no doubt that we will view the postmortem findings of lung diseases as more or less confirmatory evidence of röntgenological and surgical procedures.

But to reach this stage of perfection, the röntgenologist must be able to follow the course and progress of disease in any unusual process from its inception to its termination, either by death or recovery. It is hazardous often to solve a difficult problem in disease from a single study. Neither the surgeon nor clinician can always diagnose with any certainty as the result of one clinical examination.

Thus our problem resolves itself around a röntgen differential diagnosis in children between acute miliary tuberculosis and an acute disseminating pneumonia. To draw a finer distinction, one might say, between miliary bronchopneumonia and the hematogenous or lymphogenous miliary tuberculosis. At the present stage of our knowledge it would be rash to admit its feasibility with any surety.

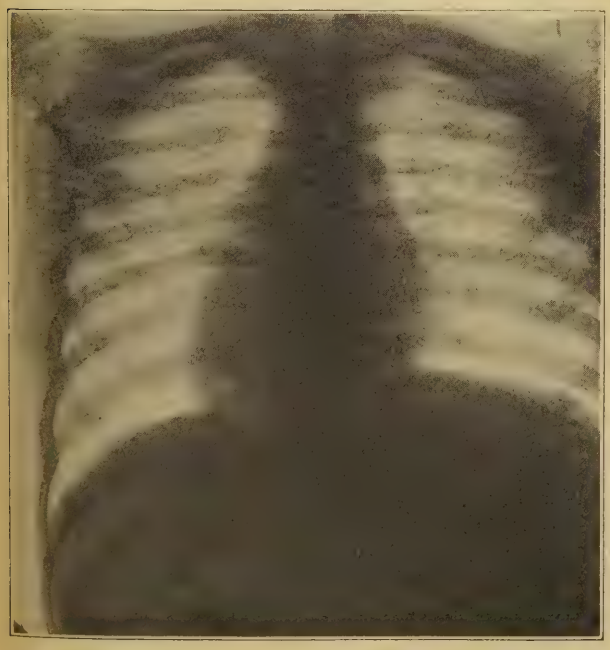

FIG. 2.—Case I. M. G. Showing the pneumonia resolving.

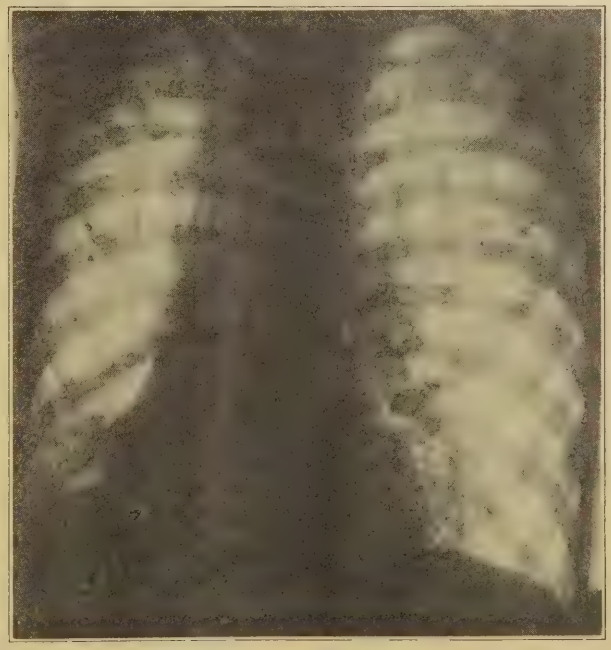

FIG. 4.—Case B. K. Mixed infection.

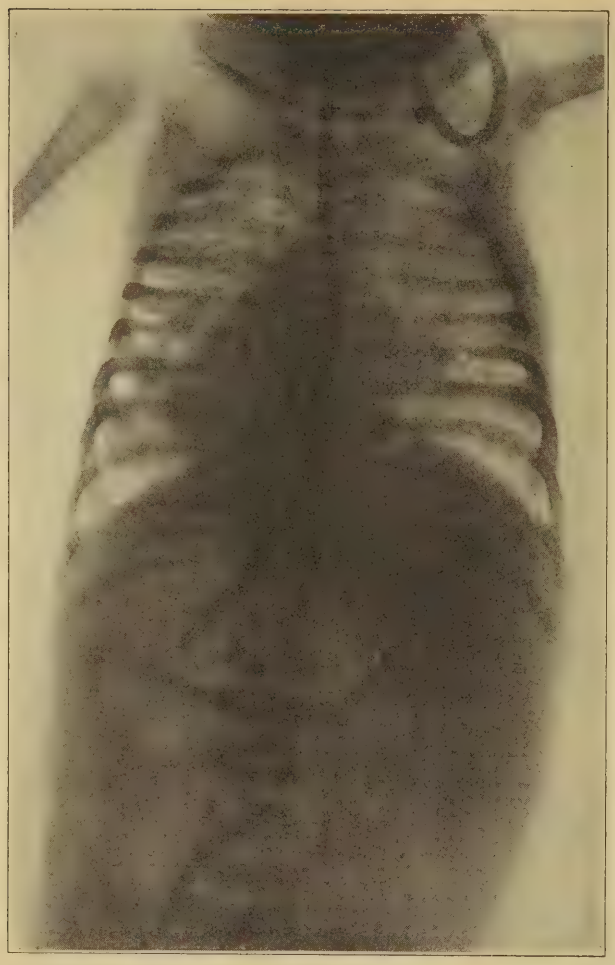

Fig. 5.—Case H. M. Tuberculous pneumonia.

Fig. 6.—Case H. G. Miliary tuberculosis.

It is conceivable, according to Jaches and others, that miliary tuberculosis may have a bronchial origin due to the transportation of tubercular secretions along the path of the bronchial tree and its subdivisions.

The röntgenogram therefore of the disseminated bronchopneumonia and the miliary tuberculosis of bronchial origin would be so strikingly similar that a differentiation must be based upon the clinical side of the case, in conjunction with the ray findings.

Investigations of Opi, Kuss, Gohn and others, confirmed more recently by Dunham, have demonstrated that the primary focus of pulmonary tuberculosis in children is in the lung parenchyma. We can demonstrate this focus röntgenologically, either in the living subject or in an artificially inflated lung secured after death. In early childhood, the apical fields are not the first attacked, and in the regional lymph nodes, the greatest reaction to infection occurs.

If one could radiograph an original focus of infection *per se,* one would observe first that one or more alveolar cells are less distinct as to air content but increased in density due to the serous exudate within them. This little pin point density increases in size as the cellular exudate occurs. The density continues to increase as caseation ensues or the soft tubercle is formed. Then the area contracts as fibrosis occurs, followed by calcification, at which stage we get the irregular calcified shadow cast by the healed tubercle.

A miliary tubercle can strictly be defined (Jaches) as a conglomeration of epithelioid cells visible to the naked eye. It is of pin head proportions, and for our purposes this evening we can consider it in the same class as soft (noncalcified) tubercles; in the acute stage, faint in outline.

When the entire lung fields, apex to base, in every lobule, are studded with these tubercles, we have true röntgenograms of acute miliary tuberculosis. The primary focus can not be detected. In fact there may be no true lung focus as it is often associated with a general miliary tuberculosis of other body organs. Each stud may be the shadow of numerous superimposed or coalescing tubercles. Caseation occurs rarely and these shadows maintain their haziness and faintness to the end, not increasing much in size.

Pure miliary tuberculosis of the lungs in children, we believe, is uncommon. It conforms more or less to the adult type, röntgenologically speaking.

The stud is denser, they are not as numerous. They may often be interstitial in location and not altogether alveolar. There may be a different development stage in different lung fields, some beginning to form and others advancing toward fibrosis and calcification. It is not this type that the disseminating bronchopneumonia simulates so closely.

In the case of disseminating bronchopneumonia reported here, only by the progressive clinical recovery were we enabled to reach the correct interpretive diagnosis—a miliary tubercle no matter what its origin, despite its location, automatically will cast a shadow similar at all times—and in picturing to you the röntgenogram of acute miliary tuberculosis, we have also drawn the picture

of the disseminating bronchopneumonia, unless there is one who dares to state that in one case the myriad tubercules are in the distant alveolar cells, while the myriads of other tubercules in the second instance are near the terminal bronchioles.

We purposely avoided describing bronchopneumonia of other types so as to be as clear and concise as possible in describing pathological shadows met with in the question under discussion.

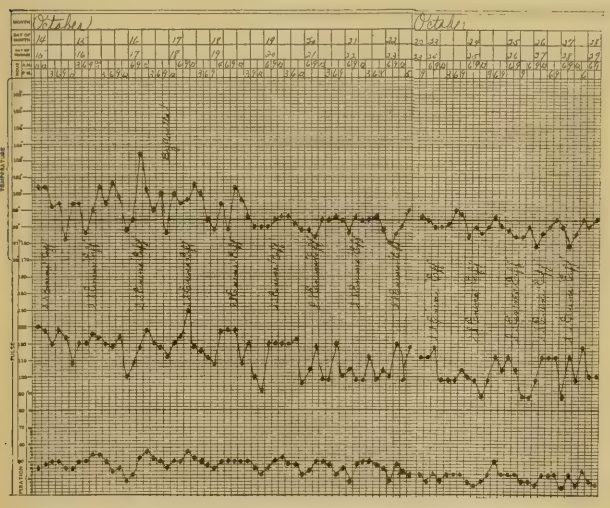

FIG. 7.—Chart showing temperature, pulse and respirations.

PROGRESS

October 16th—Child complained of slight dizziness, pleural friction rub heard in left lower axilla. Abdominal tenderness more marked and widely distributed than a few days previously. No abdominal distention condition unchanged. Cyanosis increased.

October 18th—Two attacks of epistaxis—condition unchanged.

October 19th—Some vomiting—decreased abdominal tenderness condition unchanged.

October 20th—Child stated that he felt better. Physical condition unchanged.

October 23rd—Child's condition greatly improved. Cyanosis not as marked as a few days before. Abdominal tenderness had disappeared. Spleen slightly decreased in size. Enlarged liver remained about same. Child still had severe cough. There were persistent subcrepitant râles throughout the entire chest, especially over both bases.

October 28th—There were only a few remaining subcrepitant râles at the bases of both lungs, posteriorally. Convalescent condition. All other symptoms and signs previously noted show marked improvement.

The highest temperature during the course of the illness was 102.4°. The lowest temperature 97.2. There was a characteristic evening elevation and morning remission. Convalescence occurred on morning of October 19th with a gradual return to normal. Pulse rate between 100 and 140 during height of illness; respiratory rate between 38 and 46.

DISCUSSION

The case is of interest from several viewpoints. In the first place the child's age, which was nine and one half years, is rather an infrequent period in life for this type of infection. As has been stated previously acute disseminated pneumonia properly belongs in infancy. The case was of further interest because of the widespread area of pulmonary involvement. In contrast to the usual and everyday picture as seen in a typical case of bronchopneumonia, small localized patches of normal lung was affected by consolidated areas here and there.

Life was threatened because of the marked pathology. This was evidenced and corroborated clinically by the general condition of the patient, the marked and unusual cyanosis and lastly, the extremely difficult breathing. Despite these physical embarrassments and the severity of the infection with the unfavorable prognosis, the patient survived and made a complete recovery. Again the case is of interest from a scientific viewpoint because of the readiness with which it can and has been confused with acute miliary tuberculosis.

The fever of irregular type with the characteristic evening elevation and morning remission resembled the tuberculous variety of the disease. The profuse sweats, the marked weakness, the rapid emaciation, the physical findings in the chest, the enlarged liver and spleen and the absence of the Widal reaction were points in favor of miliary tuberculosis. To this might be added the characteristic duration of the hectic temperature. Against the latter diagnosis may be mentioned the absence of a history of contact with tuberculous individuals and the certainty with which the disease could be ruled out in the patient. There were no tubercle bacilli found in the sputum. The enlarged liver and spleen so well presented by the patient during the height of the infection were in all probability caused by the toxemia. It is fair to assume that several bacilli became lodged and localized in these organs from the general circulation. It is only necessary to recall the function of the liver as the great detoxicating station of the human mechanism. The strongest argument against acute miliary tuberculosis is the fact that the child was completely restored to health. This conclusive evidence is borne out clinically, despite the hopeless outlook rendered by the x ray studies.

The treatment was largely expectant. Drugs were used judiciously as conditions arose and warranted therapy. Active stimulation and supportive treatment for the heart were instituted early. An abundance of fluid was made imperative from the start. Counter irritation over the chest, occasionally a sedative for excessive coughing and general treatment for hyperpyrexia were the salient points in treatment. Nutrition consisted of a light and easily assimilated diet.

SUMMARY AND CONCLUSION

1. Acute disseminated bronchopneumonia is rarely seen. The condition is infrequent in children.
2. The case report as presented occurred in a boy whose age was nine and one half years. Life was endangered both by the severity of the infection and the enormous pathology.
3. Because of the closely allied symptoms and signs found in acute miliary tuberculosis and of the x ray studies the diseases are often confused.
4. The individual made an uninterrupted recovery primarily because of his natural immunity aided by competent medical supervision and nursing care.

Tracheobronchoesophagoscopy

WILLIAM BEVERLY WHITE, M.D.
Stamford, Conn.

The pioneering of this particular branch of surgery received its first impetus through the efforts of A. Kirstein, who by means of a tubular instrument obtained a direct view of the vocal cords and the bificuration of the trachea. About two years later Killian removed a foreign body from the bronchus of a patient. This demonstrated the possibilities of this specialty. He then developed a technic which is the ground work of our several modifications.

The instruments which are most popular in this country are the Jackson tubes, which differ from the Brunning tubes in several ways, but the main difference is that the light is at distal part of the Jackson tube, while the Brunning tubes have it at the proximal end and are larger in diameter.

Foreign bodies are aspirated in various ways but the greatest contributing factor is either carelessness or ignorance on the part of the parents, allowing their children to obtain objects which if swallowed may cause serious trouble. As the intruder comes in contact with the pharynx there is a sudden inspiration during which time the glottic chink is wide open, allowing the object to drop into the air passages. The paroxysm of coughing following is Nature's method of endeavoring to dislodge the intruder. The irritant action of objects in the air passages will many times depend on its chemical composition.

Once the intruder has passed below the vocal cords it is rarely that the expulsive coughing will dislodge the foreign body so that it may be expectorated. Hence follows the usual symptoms of foreign bodies in the air or food passages.

At this point, I wish to digress long enough to condemn the digital probing method., i. e., feeling around the pharynx and hypolaryngeal region with the finger, hoping to find and remove the intruder, the ill results of which we see too often, and is the cause of some of our serious complications.

Peroral endoscopy was the direct means of opening up new fields in diagnosis and operative procedure, among which we may merely mention irrigation of pulmonary abscess, dilatation of stricture of trachea and bronchi. Such operations could not be undertaken were it not for the ingenious instruments conceived by Jackson.

All cases that give histories which suggest some disturbance of either the air or food passages should be more carefully studied and examined. Many of these cases can be diagnosed and treated successfully by means of endoscopy.

For the sake of brevity, except where we wish to add emphasis, we have omitted considerable case history, x ray findings and other examinations.

Case I.—C. D., aged six months. Family thought the patient choked on a piece of meat given five days previously. When admitted, the patient had a temperature of 103° and physical signs showed bronchopneumonia. Laryngeal examination showed marked edematous condition of the cords and arytenoids. This was sufficient mechanical disturbance to account for the symptoms, nevertheless we did a bronchoscopy. With the tube *in situ,* breathing was greatly relieved. Unable to find any foreign body and with the removal of bronchoscope patient again showed signs of laryngeal embarrassment, therefore we did a tracheotomy, immediately after which the baby went to sleep, apparently greatly relieved. This continued for twelve hours, then the patient's condition became worse and he ceased to breathe a few hours later.

This case brings to your attention a point which we cannot emphasize too emphatically, namely, digital probing, meaning the probing with the fingers around the pharynx and even the larynx, hoping to feel and remove the foreign body, as happened in this case. There can be no doubt that this was a case of suspected foreign body.

Case II.—W. B., a child aged two years. Parents were under the impression that he swallowed "something that interfered with breathing." The family physician resorted to the usual manipulations, as digital probing in the hyperlaryngeal area. When this patient was admitted to the institution he was experiencing considerable difficulty in breathing. Examination of the larynx and adjoining tissues was a most striking example of unwarranted traumatism to these delicate laryngeal tissues.

Bronchoscopy failed to show any foreign body. The patient was returned to the ward and kept under observation for several days and then discharged. The condition of the larynx was the cause of all respiratory embarrassment, due to the overzealous digital examination. Discharged cured.

Case III.—L. B., aged three years, x ray showed safety pin open point downward third dorsal vertebra. Safety pin removed. This patient also had been unwontedly traumatized on account of the overzealous parents using digital probing. Discharged cured.

Case IV.—L. J., aged seven months, parents had no knowledge of patient swallowing a foreign body. Referred on account of restlessness and coughing. Preceding examination patient given large dose of paregoric as a means of quieting him. Examination showed a piece of peanut shell located below the vocal cords and fitting tightly on the trachea. Due to size of the foreign body which had absorbed considerable moisture, it was impossible to get the shell in the tube and withdraw it safely. Therefore performed a low tracheotomy and removed peanut shell through opening. Two days later removed tracheotomy tube and patient was discharged in four days.

Case V.—D. F., aged seven years, while running to school several days ago tripped and fell face downward on the ground and accidently inhaled a grass burr, the most pertinent symptom was wheezing during inspiration. The burr noted on posterior wall of trachea immediately above its bificuration. The burr was removed and the patient made an uneventful recovery.

CASE VI.—J. T., aged seven years, one week previous to admittance put some grass burrs in his mouth. While in the act of expectorating them he accidently inspired one of them into his air passages. Immediately was seized with a paroxysm of coughing, which continued for two days at varying intervals. The wheezing inspiratory sound was present in this case as in the previous mentioned, but otherwise did not show any ill result from the burr. Burr removed about one inch above the bificuration and adhering to the posterior tracheal wall. Result, recovery.

CASE VII.—I. C., aged six months, parents think patient swallowed small sliver of wood which was interfering with its respiration and nursing, x ray showed a foreign body of a metallic nature about the third dorsal vertebra. Intruder located just below cords. Small tin star was removed. Recovery.

CASE VIII.—G. H., aged three and a half years, a few hours previously the patient had swallowed a small metal cow which was found in a well known brand of popcorn package, as a prize. There was little respiratory embarrassment. X ray foreign body in trachea third dorsal vertebra. Small metal cow removed. Result, recovery.

CASE IX.—Mrs. M., aged thirty-five years, while eating rice pudding was seized with a paroxysm of coughing and choking, thought she swallowed a raisin which was causing the trouble. Examination revealed an intruder in the posterior pharyngeal wall immediately above the larynx. A straight pin which was head downward, firmly embedded immediately above the larynx, was removed. The patient made a complete recovery.

CASE X.—Baby J. J., aged one year seven months, swallowed a piece of corn three days previously, since then had intermittent coughing seizure and difficulty in breathing. Bronchoscope inserted and noted piece of corn, conical end upward, firmly impacted in right bronchus, grasped the intruder but each time the forceps would slip off. After several trials withdrew the forceps and bronchoscope to adjust for more firm grasping. Assistant informed me that patient ceased breathing; immediately did a low tracheotomy and with considerable effort removed the corn from its impaction. All artificial respiratory methods were of no avail. This was not a case of asphyxia as the intruder was firmly lodged in right bronchus. It was a combination of several factors in which the age of the patient, instrumentation plus the nature of the intruder, for as we all are aware, foreign bodies of the vegetable kingdom are more to be feared than any other class of offenders, all of which contributed to the fatal outcome.

CASE XI.—W. P., aged seven and a half years, three days previously while eating popcorn was suddenly taken with a paroxysm of coughing which continued for some time. Bronchoscope was passed and noticed foreign body adhering to trachea and just above the bificuration endeavored to grasp it but with each inspiration it would flatten out against the trachea and momentarily would be lost. Finally got the lip of the tube just in front of it and with the next expiratory blast it was blown into the tube. Foreign body was the transparent covering of the piece of corn. Result, recovery.

CASE XII.—R. C., aged three years, swallowed a piece of green peach. There was some difficulty in breathing, also coughing. The piece of peach was removed from right bronchus. Recovery.

CASE XIII.—B. C., aged fourteen years, swallowed a nickel two days previously, and had difficulty in retaining food. Removed a nickel from the esophagus about third dorsal vertebra, immediately below the foreign body was a pronounced narrowing of the lumen of the esophagus. Later history revealed that child had swallowed concentrated lye ten years ago. Recovery of foreign body but patient failed to return for dilation of stricture.

CASE XIV.—A. C., aged thirty-six years, complaining of irritation on right side of throat and hoarseness. Laryngeal mirror failed to show the cause of the symptoms, but when examined by means of laryngoscope noted papilloma attached to right cord. This we removed at a later date. The patient made a good recovery.

CASE XV.—P. T., aged two years, difficulty in swallowing for two days, also hoarseness, it was suggested that the case might need intubation as diphtheria was suspected. It is our practice in all diptheritic cases to examine the larynx before intubation. Examination showed large abscess just above and involving the laryngeal tissues. This was opened and tracheotomy performed. But patient died later from exhaustion.

CASE XVI.—D. S., aged thirteen years, swallowed some concentrated lye, eleven years ago. Now has difficulty in retaining fluids. By means of x ray and esophagoscope, located stricture, dilated same. Condition improving.

CASE XVII.—Mrs. I. Difficulty in swallowing for two months, but recently had been able only to take liquids, x ray shows mass encroaching on esophagus. By means of esophagoscope noted compression, also that mass did not involve the esophagus, this is perhaps a malignant condition of media stinum.

CASE XVIII.—T. J. O., a physician, who while eating his lunch very hurriedly, accidentally swallowed a piece of bone, immediately experienced pain in swallowing, the same radiating behind the sternum. X ray and esophagoscopy negative but we noted the abrasion of the posterior wall of the esophagus, which was no doubt the point of contact with the intruder. Patient was instructed to be quiet for a couple of days, also put on a liquid diet and bismuth subnitrate and discharged three days later.

CASE XIX.—Mrs. L. R., adult female, aged thirty years, thought she swallowed a fishbone; had the usual symptoms. X ray and esophagoscopy negative as to foreign body, we were able to note the cause of her symptoms, namely, the small abrasion on the wall of the esophagus. She was treated as the case above and made usual recovery.

CASE XX.—H. A., aged two years. Two days previously patient swallowed concentrated lye. Now having difficulty in retaining fluids. Examination showed most of damage in mouth and pharynx. The patient was returning for dilatation treatment of the esophagus.

CASE XXI.—O. W., aged twenty months. Four months ago swallowed some lye, now regurgitating food, unable to retain any fluids. Diagnosis stric-

ture of esophagus, gastrostomy performed, lated dilation with No. 270 French. Improving.

Case XXII.—M. B., aged five years; three years previously swallowed some lye, having difficulty retaining food. Diagnosis stricture of esophagus. Dilation twice weekly. Improving.

Case XXIII.—A. B., aged twelve years, eleven months ago swallowed concentrated lye, regurgitating food. Patient very much emaciated, unable to retain fluids. Diagnosis stricture of esophagus. usual dilation treatment, progress unsatisfactory.

CONCLUSION

The foregoing cases have been selected to demonstrate the variety of conditions which come under the observation of men doing this line of work. The removal of foreign bodies many times taxes our ingenuity but the results are most satisfactory. Cases which have strictures of the esophagus following the ingestion of concentrated lye are many times apparently hopeless but patience and prolonged dilation have been the means of restoring to good health a number of these unfortunate children.

The Bronchoscopic Treatment of Bronchial Asthma and Chronic Bronchitis with Case Reports

J. PAUL DE RIVER, M.D.

San Francisco, Calif.

Medical science dates from time immemorial and, were we to make a careful study of its scientific advancement, we would find that the progress could be attributed largely to the development of the mental faculties of the human race through education and environmental circumstances during its evolution. Although our present day method of medical practice is not *per se* an exact science, it may be considered as such from a practical viewpoint. I do not believe that any other branch of science has been subjected to such a tremendous amount of adverse criticism and yet continued to progress steadily. However, the science of medicine may be likened to many other sciences in that the development of many new discoveries can be traced to the untiring efforts, acumen and ingenuity of an individual, who often through necessity, has converted his imaginations into practice or, through deep study of some particular case and assimilation of ideas, has contributed some new method of scientific value.

The development of the laryngoscope in 1854 by Manuel Garcia added interesting chapters to medical history, and besides, opened up a new field for scientific investigation of a heretofore obscure region of the human body. Forty years later, in 1894, Kirstein described his method of direct laryngoscopy, which was followed shortly by a description of tracheoscopy by Kirstein and Mikulicz. In 1897, Killian developed upper bronchoscopy and, after a brief period, made a report on lower bronchoscopy. In 1904, Jackson introduced his instrument. His contributions to medical literature have been many, and his mechanical skill has been unsurpassed.

I believe that the medical profession, in general, are prone to think of bronchoscopy in synonymous terms of "Jackson," "bronchoscopy," and "foreign body." But we must also bear in mind the conspicuous ability and valuable contributions in this field of Bruening, Lynch, Lynah, Yankauer, Mosher, Carmody and a score of others deserving of recognition. Medical literature is voluminous with contributions from the foremost authorities, relating to the etiology, symptoms, diagnosis and treatment of almost every known disease. Albeit, when all is summed up, we realize how meager man's knowledge is, and how limited his ability accurately to diagnose and properly treat many of our common ailments. This can best be judged by the mortality statistics and autopsy findings and is largely due, I believe, to our limited ability to study tissue changes of many organs, during life, because of their obscurity and our desire to avoid exploratory operations because of surgical shock. We, therefore, depend largely on necropsy findings which, in many instances, give an entirely different picture at postmortem from that which is observed during cell life. The gross pathology is different.

Bronchoscopy, as applied to diseases of the respiratory system, opens up a vast field for diagnosis as well as a means for the application of direct therapy in respiratory diseases. As an aid to the internist and thoracic surgeon, it is of proved value. The method of treating pulmonary suppuration, as reported by Yankauer in 1916; *Lung Mapping* published by Jackson in 1918 and the writing of Lynah in 1921 on the localization of lung abscesses, have cast a new light on diagnosis and treatment that before was but vaguely understood. I shall not dwell on the many conditions adaptable to bronchoscopic study and treatment, nor touch upon the technique of bronchoscopy which has been so completely described by our teacher, Dr. Chevalier Jackson. But I should like to say again that, by the use of the bronchoscope in the diagnosis and treatment of diseases of the respiratory tract, we are able to observe directly, gross pathological changes occurring in the living tissue, and to make applications to the diseased parts, or to secure proper drainage when indicated. I do not mean to imply that bronchoscopy is a panacea for all respiratory diseases; it is merely an important adjunct in the treatment of these diseases and, in many instances, it far surpasses all other methods that the armamentarium of surgery now possesses. In the treatment of bronchial asthma and chronic bronchitis, a brief report of which I made in the New York Medical Journal and Record in

February, 1924, I am thoroughly convinced that the value of bronchoscopy, in the aforesaid conditions, is unlimited, for without the aid of the bronchoscope, many pathological conditions would remain in obscurity and untreated. The medical profession has been slow to realize the usefulness of the bronchoscope and the importance of close cooperation between internist, thoracic surgeon and bronchoscopist.

In the remaining portion of this article, I shall discuss bronchoscopy as I have practiced it in the treatment of bronchial asthma and chronic tracheobronchitis. Assuming that we all are familiar with the theories of the etiology of bronchial asthma, I will not approach this immense field which comprises volumes of medical history.

Bronchoscopic observations and treatment, as carried out in twenty-two asthmatic cases, presented a diversity of symptoms, comprising the well known asthmatic syndrome, diagnosed clinically as bronchial asthma. All but one patient had chronic bronchitis, resulting from inhalation of poisonous gas in the World War or from influenza, and attributed these to the asthmatic condition. One patient gave no history of influenza or pneumonia, and had seen no military service because of poor physical condition. Before starting bronchoscopic treatment, all patients were thoroughly examined physically; bacteriological examinations were made of sputum for the tubercle bacillus, Wassermanns were taken and radiograms made of the chest; tonsils, teeth and paranasal sinuses were carefully searched for foci of infection and when such were found, proper methods of surgical treatment were carried out. Only after other means had been tried without success—such as proper diet and hygiene—were these patients bronchoscoped.

On numerous occasions, I have had the opportunity to insert a bronchoscope during the height of an asthmatic attack. In performing bronchoscopy, I first anesthetize the postpharynx, epiglottis, vocal cords and pass the swab well down into the trachea, using ten per cent. cocaine. This procedure will facilitate the passage of the instrument. A Jackson bronchoscope, aspirating type, is then introduced and, through this instrument, one is able to remove any exudate that is adhering to the walls of the trachea and bronchi and to make accurate, direct applications to all inflamed hyperemic areas, as well as to atomize the entire tracheobronchial tree with a medicated solution. (I have been using adrenalin inhalant, which is an oily solution and very soothing to the mucosa.) For local application to the hyperemic areas, I have used with best results, a ten per cent. silver nitrate solution, although argyrol and silvol have been tried. The bronchoscopic picture encountered, especially during or immediately following an attack of asthma, is as follows: there is generally a thick mucopurulent exudate, strongly adherent to the walls of the trachea and bronchi, with one or more inflamed areas or patches, the favorite site being at or near the bifurcation of the trachea. One case presented a highly inflamed trachea, the inflammation extending well down past the bifurcation of the trachea. In every case, which was bronchoscoped during an attack, the mucosa presented a swollen or waterlogged appearance, and upon inserting the bronchoscope and applying adrenalin solution, there was an almost instantaneous relief experienced, with a rapid cessation of the attack, followed by copious expectoration of thick tenacious sputum, which lasted for several days. In all asthmatic cases under treatment, it has been my experience to find an accompanying bronchitis. Whether the bronchitis was the cause of the asthma, the result of it, or whether the two are interdependent, I am unable to state definitely. But, from observation, I am inclined to believe that the two are interdependent conditions and that the bronchitis should be treated, even though the asthmatic attacks have been completely eradicated.

The bronchoscope is of great value in the treatment of chronic tracheobronchitis after the internist has exhausted his efforts to relieve the patient. Many cases may be benefited by bronchoscopy plus medical treatment, including the administration of vaccines. In a series of twenty-eight cases, a large percentage was the result of inhalation of mustard or phosgene gas, and the remainder the result of influenza. The sputa were negative for tuberculosis in all cases. The solutions used for direct applications were argyrol ten per cent. to twenty per cent., glycerotannate ten per cent., mercurochrome five per cent., silver nitrate five to ten per cent., and chloretone and adrenalin inhalant, all of which have their value, depending largely on the bronchoscopic picture encountered and the judgment of the operator. The bronchoscopic picture observed, upon examination of patients whose ailments were the result of gas inhalation, is vastly different from those with bronchitis following influenza. In the gas series, the entire respiratory tract, from the larynx down, presented a beefy red appearance, highly injected. The tracheal rings standing out prominently and intensely white, furnished a marked contrast to the injected mucosa. Usually there is a profuse mucoid exudate covering the walls of the bronchi, with scattered areas of scar tissue. The series of bronchitis cases following influenza show a different picture. Here, the mucosa is of a bluish gray appearance, with areas of old fibrosis. The lumen of the bronchi are generally diminished in size, due to what is an apparent edema. The secretions are profuse and usually of a mucopurulent character. There seems to be a loss of muscular tone, and an interference with ciliary action, which allows the secretions to stagnate. Much good can be accomplished in these cases by bronchoscopic drainage and local applications of a solution which will stimulate the mucosa and cause shrinkage of the lumen of the smaller bronchi. And, by aspirating, we are able to remove the excessive secretions, thereby allowing the lung to be properly aerated.

Bronchoscopy is no longer limited to the removal of foreign bodies, but occupies a rightful place in the diagnosis and treatment of diseases of the respiratory system. Its application is not only of value in the diagnosis and treatment of diseases of the tracheobronchial tree, but may be used in certain lung conditions as well.

It is one of the few methods by which gross pathological changes may be accurately observed in the living tissue in the obscure regions of the human body.

Where there is pus, there should be drainage and,

in certain cases, this is best accomplished by bronchoscopy.

In my series of bronchial asthma cases, there was a coexisting chronic bronchitis, which required treatment between the asthmatic attacks. I believe that, by benefitting the chronic bronchitis, we do a great deal toward completely elevating bronchial asthma. In asthmatic cases, we should aim in every way to facilitate drainage of the viscid secretions, and this can best be accomplished by bronchoscopy.

Bronchoscopy is only an adjunct in the treatment of the aforesaid conditions. Rest, climate, hygiene, diet, vaccines and elimination of all foci of infection play an important part, and should be carried out along with the bronchoscopic treatment.

Adrenalin is of recognized value in the treatment of bronchial asthma. But I agree with the observations of Ephraim that intrabronchial administration of the drug is much more effective and lasting than its use by another method.

In the treatment of chronic tracheobronchitis, resulting from inhalations of irritating gases, much relief can be given to the patient. However, in my brief series of cases, I have not effected a complete cure.

The author's references will appear in his reprints.

Report of Three Cases of Abscess of the Larynx*

J. COLEMAN SCAL, M.D.

New York

These cases are reported because of their infrequency and the high mortality of this condition when not recognized early. The etiology of the condition is usually idiopathic. Traumatism of the larynx, inhalation of noxious vapors and exposure to wet and cold are some of the causes cited by various authors. The most probable cause however is a slight injury, occurring while eating, at the base of the tongue or spreading from the lingual surface of the epiglottis to the root of the tongue on the aryepiglottic folds.

The usual site for this condition is where the mucous membrane is loosely attached, such as the anterior surface of the epiglottis, aryepiglottic folds and arytenoid cartilage. In children this condition may be caused by infectious diseases of childhood and is usually mistaken for a retropharyngeal abscess.

Case I.—D. P., aged thirty-eight, tinsmith, felt well until three days before examination, when in tearing down a chimney he inhaled gas, soot and dust. On the following day he commenced to feel uncomfortable, complained of general malaise, hoarseness and painful swallowing. Upon examination, the patient appeared apprehensive, somewhat dyspneic and hoarse. Intense pain was referred to the larynx.

Upon indirect examination of the larynx, the epiglottis, the aryepiglottic folds as well as the entire mucosa of the left side appeared red, swollen and somewhat edematous. A well defined circumscribed mass could be made out at the left side at the base of the epiglottis. The view to the larynx was obstructed.

A bayonet shaped paracentesis knife was plunged into the mass, releasing a quantity of yellowish pus. Instant relief was experienced. The next day examination showed a subsidence of all symptoms, and the patient was entirely well in four days.

Case II.—L. T., aged forty-eight, housewife. Previous history negative. Four days prior to examination she awoke complaining of sore throat and painful swallowing. These symptoms increased, and in addition she complained of a choking sensation and commencing hoarseness. Upon examination the patient appeared to be extremely ill; her tongue was coated, temperature 101°, swallowing and talking were painful. There was slight hoarseness present. Upon palpating the larynx pain was experienced at the right side when pressure was exerted from the left to the right. Upon indirect examination of the larynx a reddish mass, the size of a pea, was plainly visible between the epiglottis and the base of the tongue. There was no edema of the epiglottis. The left aryepiglottic fold and left side of the larynx was red, somewhat edematous and of a glassy and transparent appearance.

On June 1st the patient was referred to the Beth Israel Hospital where the abscess ruptured spontaneously on the day of admittance; the symptoms immediately cleared up. The patient left the hospital on June 4th and was discharged cured on June 8th.

Case III.—S. S., aged forty-five. Previous history negative. Stated that without apparent cause swallowing became painful, the pain radiating towards the right ear. Upon examination two days later hoarseness and commencing dyspnea had set in. In examining the throat, by pressing the tongue down, a transiently visible swollen and edematous epiglottis was revealed. Upon indirect examination of the larynx, a bilateral diffuse swelling of the mucous membrane was visible. There was no abscess formation, the epiglottis was edematous but not ulcerated. Direct examination was refused. A diagnosis of laryngitis with commencing abscess formation was made and the patient referred to the hospital. Due to some misunderstanding, however, he was not admitted to the hospital but returned home and applied local treatment in the form of hot gargles and applications. The following day the patient reported he had a gush of blood and pus from his throat, which was followed by immediate subsidence of symptoms.

In conclusion, this condition should be always considered a serious disease which may end by suffocation or by involvement of the lungs or mediastinum or by septicemia. Where the condition is secondary, the primary disease causing this edema and abscess should receive proper attention.

The Etiology of the Common Cold

ALGERNON BRASHEAR JACKSON, M.D.
Washington, D. C.

Up to a few years ago there was not much attention paid to the common cold except to record its presence as annoying and its absence the result more often of good luck than of good judgment. About two years ago a physician in Texas told me that he had never learned to even spell the word coryza, until he began writing prescriptions for Spts. Frumenti, nor had he ever dreamed that its presence was so universal.

From the viewpoint of the public health the so-called common cold is a definite factor in reducing the hours of man's efficiency and piling up considerable economic loss. Add to the economic loss the usual loss of temper and you have a factor in human behavior which must be reckoned with. So we have set about to determine the cause of coryza with the idea of offsetting its prevalence and reducing its high mortality rate upon man's normally sweet disposition.

In the earliest writings can be found evidences that the noses of mankind have run as the result of catarrhal discharge following the coryza or common cold ever since man has kept a record of his performances. From the time of Hippocrates to the present day we have all been inclined to charge the cold up to meteorological causes, even despite the fact that we now recognize most such epidemics are usually due to specific bacteria. After a tremendous amount of work done by many and various investigators the general consensus of opinion is that there is no one organism which may be regarded as specific in causing the common cold. The flora of the nose and throat is never constant in and out of disease.

For several years in conjunction with the United States Public Health service we have carried on certain investigations regarding the minor respiratory diseases among the students of Howard University. In many instances these studies have been both interesting and disappointing, yet we have been able to reach certain conclusions. Always interesting it is to have the student tell you just how he "caught his cold" a sort of game which most persons enjoy. The various stories of sitting in cold rooms, sitting in churches underheated and damp, getting warm from exercise and cooling off too suddenly, attending a close, stuffy, moving picture house and wearing insufficient clothing are always taken as bearing much weight in the matter of etiology. Sudden changes of weather always come in for accusation by all persons who contract cold and we have come to regard this factor as rather constant. A rather careful examination of the nose and throat of all students revealed the fact that those who had enlarged turbinates, deflected septa, hypertrophied tonsils and adenoids always had more colds than those possessing a normal nasal mucosa. Not only did they have colds more frequently, but they contracted them more easily. We have found it very difficult to impress upon the average student the serious consequences which may follow the common cold, but the few whom we could persuade to have operations upon the nose and throat have improved in the matter of frequency and susceptibility to attack.

But still we are a long ways from the specific cause of the common cold. Bacteriological findings are never constant and include the Micrococcus catarrhalis, staphylococcus, streptococcus, Bacillus influenza, pneumococcus, the Bacillus of Friedlander and others, yet to no one of these can the common cold be charged. The students who come to Howard University represent such a wide geographical distribution that this institution affords a most unique opportunity to study the matter of climatic adjustment and the part it plays as an etiological factor in producing the common cold. Strange to say however this played a small part in the matter except where we found definite nasal pathology. In fact normal students from warmer, higher and drier climates than that encountered in Washington weathered the season better than the native students who had either mild or advanced nasal pathology. Therefore we come to the conclusion that no proper index to frequency and susceptibility to coryza can be reached without a careful examination, study and record of treated and untreated nose and throat conditions.

Certain observations lead us to believe that there are two types of coryza, the infectious and the noninfectious. Just recently through experiments upon volunteers we have come to a pretty definite conclusion that our earlier observations are correct. Also we observed that no cold was infectious, in its incipiency or during its first twenty-four hours, but some are and others are not after forty-eight hours duration. Thus we concluded that bacteria as an etiological factor are practically nil except as secondary invaders or upon the increase of virulency consequent to a pathological disturbance of the mucous membranes. Even in this instance no one organism can be regarded as specific because they are too variable and inconstant as to type, and they are infectious only in that they find a soil prepared for their invasion—but from other causes than bacteria. This hypothesis may not endure yet up to the present our experiments seem to point in the direction that each and every cold is to be regarded as an anaphylactic shock of varying degree as the result of the parenteral ingestion of some foreign protein through a nonresisting nasal mucous membrane. That foreign protein may be of bacterial origin or it may come from other sources finding its way most naturally to the nasal mucosa through the atmospheric route. This would account for the sometime infectious and the other time noninfectious nature of the common cold.

The literature of today is so filled with theories which aim to set us right upon the whole matter of infection, that we shall not enter into a discussion as to the merits of each, yet believing that all have a certain sound basis from which shall spring an entirely new knowledge of this most important sub-

ject. We, however, believe that the whole matter of immunity and infection rests in the ability of the tissue cells to combat through their proteolytic enzymes the invasion of both specific and nonspecific foreign proteins, or let us say bacterial and nonbacterial proteins. Health or disease (especially that which we call infectious) is always the result of the successful or unsuccessful war waged by the body cells through their power to digest and appropriate foreign protein completely or incompletely. Abderhalden has proved that within twenty-four hours after the injection of a foreign protein that proteolytic enzymes are found in the serum, and normally they are not found there. It is generally conceded that all antibodies (and we like the word interceptors better) which find their way into the body fluids originate in the tissue cells. Surely these interceptors or antibodies must have a specificity in tissue cell origin in order to combat and digest the protein for which that cell has a positive chemotaxis. Yet nonspecific protein therapy appears to prove that these interceptors may be stimulated and educated to resist the invasion of certain foreign proteins. Thus the degree of immunity depends upon the affinity the body cells have for foreign protein and the ability of the interceptors to select and appropriate from the complex protein molecule through cleavage to that stage of amino acid which is not only harmless to, but made useful by the tissue cells themselves. Incomplete cleavage or digestion of the protein molecule sets free toxic products which result in tissue irritation and disease.

The experiments we made regarding the etiology of the common cold helped greatly to convince us as to the truth of the above mentioned theory. To a great degree we followed out the line of experiment conducted by Mudd and Grant and reported in the *Annals of Otology, Rhinology and Laryngology* of March, 1921. A number of volunteers divided into two groups, one apparently normal and the other with decided nasal pathology, were exposed to a series of conditions usually regarded at least as contributing factors in the etiology of colds. During rather warm weather they were placed in a draft created artificially by an electric fan, immediately after walking rather rapidly for four or five city blocks. This exposure lasted for fifteen minutes during which time all began sneezing and blowing their noses, and in each the nasal mucous membrane recorded a drop in temperature from 1 to 1.5° C. and showed a marked vasoconstriction and ischemia. Wet towels applied to the back of their necks produced practically the same results, which were exaggerated when they were placed in the draft of the electric fan. At another sitting the draft was directed over the feet and legs and continued for about thirty minutes before sneezing began. The temperature reduction and ischemia were even then not so marked as in the other two experiments. Immediately after exposure these persons were properly wrapped in blankets and allowed to walk and sit around in a normal way. Then it was observed that the symptoms of coryza disappeared in from one half to one hour from the normal individual and lingered from twelve to twenty-four hours with those who had a decided nasal pathology. The normal individuals were subjected daily to the same sort of tests and on about the fourth or fifth day they developed a decided immunity and refused to show any symptoms of coryza. This we attributed to the fact that they had established a tolerance to the foreign protein, thus having become desensitized. Those with nasal pathology were put through the tests every forty-eight hours and reacted more slowly in the matter of reaching the refractory state, but eventually they all did.

These experiments seem to point out to us that the chilling of the nasal mucous membrane through exposure produces a vasoconstriction and ischemia which in turn lowers the proteolytic activity of these localized cells. Thus protein cleavage is but partial and incomplete thereby allowing the toxic product following this faulty enzymatic action to enter the contiguous sensitized cells and produce a mild anaphylactic shock which we term coryza. The incubation period and the duration of a cold are always in direct ratio to the suddenness of the chill administered and the recuperative power of the nasal cells in regaining their disturbed enzymatic action. In those persons with distinct nasal pathology (which is always more prevalent than one is inclined to believe) their tissue cells are less active and the hypertrophic condition exposes a larger field to the action of foreign proteins, thus making them always more susceptible to anaphylactic shock or coryza. This also must be regarded as a very definite contributing factor in bringing about the more serious sinus infections and otitis.

Working on the thory suggested above a new group of volunteers was selected for further experiments, all of whom were free from any nasal trouble, yet gave histories of catching cold easily and during each fall, winter or spring having at least one attack. Three received prophylactic injections of a stock vaccine containing the varied organisms usually thought to be associated with the common cold. Three received prophylactic injections of a nonspecific protein manufactured by a reliable house but not recommended for the use to which we were putting it, viz., as a prophylactic against coryza. All six volunteers were exposed to the same drafty treatments mentioned above with a result which is especially interesting and highly suggestive. The first day's exposure brought symptoms from all who had received the bacterial vaccine and from only one who had received the nonspecific protein injections. The second day's exposure showed that still all three who received the vaccine sneezed and showed symptoms of cold while none who received the nonspecific protein showed any symptom, though kept exposed for five minutes longer than the other group. On the third day's exposure for fifteen minutes none of either group manifested any symptoms except chilling of the mucosa and accompanying ischemia.

These rather suggestive data appear to hint at possibilities for further studies not only regarding the etiology of the common cold but all processes which we regard as infectious. We propose next spring and summer to try desensitizing hay fever victims by prophylactic injections of nonspecific protein. There is a possibility that more careful and painstaking study of the common cold will open up a better and more comprehensive knowledge of the whole matter of infection.

Historical Medicine

Kenelm Digby: Amateur Physician

LOUIS J. BRAGMAN, M.D.

Syracuse, N. Y.

I.

Critical judgment by the contemporaries of Sir Kenelm Digby was decidedly more severe and less tolerant than the opinions accorded him today. Evelyn (1) stigmatized him with an epithet that has clung tenaciously as "an arrant mountebank." Henry Stubbes (1) labelled him "the very Pliny of our age for lying;" and with a faint touch of feminine kindness Lady Fanshawe (1) referred to his "infirmity" of falsifying reports of his scientific experiments. As a consequence of his supposed weakness in that direction he was made the recipient of much scorn and ridicule.

A review of the accomplishments of this energetic seventeenth century knight affirms, however, that it was his credulity rather than his infirmity which drew him towards so many of his ludicrous conclusions. Christopher Morley (2), whose contacts with the literary sidelights of Digby are so well known, protested that he should not be considered a mountebank or a charlatan, but instead "one who had a genuine scientific zeal for medical dabblings." Similarly, S. K. Lee (1), his biographer, wrote him down as a shrewd observer of natural phenomena, and a scientific amateur in contradistinction to a true man of science.

He was, of course, in the strictest sense neither a physician nor a surgeon, and his legitimate bond to the profession consisted chiefly in his additions to philosophical medicine. The bold manner in which he felt free to suggest new lines of practice would be loudly decried today, yet he represented, according to Richardson (3), an illustrious example of the "order of generally useful men, pioneers of science in her practical applications." And in frontier days is there to be desired a better type?

Digby had a broad enough knowledge of the natural sciences to earn for him a Fellowship in the Royal Society. His treatise *Of Bodies* (4) revealed a capable fund of information on plant and animal physiology, and he is believed to have been the first one to explain the need of oxygen in the cycle of plant life. Another noteworthy contribution was the demonstration of the practical value of lip reading in teaching deaf mutes to speak.

His deep interest in the problems of mankind was particularly shown when he urged Descartes to abandon his philosophical speculations and to direct his attentions towards the study of the human body and the means of prolonging life. His two posthumous publications, *Choice of Experimental Receipts in Physick and Chirurgery,* and *Chymical Secrets and Rare Experiments in Physick and Physiology,* cite further the investigating trend of his mind.

The name of Kenelm Digby is invariably associated with "the powder of sympathy" (5), which consisted of blue vitriol prepared in a very ritualistic manner as detailed by Hartman (6), his steward and laboratory assistant. This balm was accredited with the power of curing an injury if applied to the blood stained garments of the wounded person, or even to the weapon originally responsible for the trauma.

This one time popular nostrum in later years subjected its sponsor to much disparagement. Nevertheless Morley (2) expressed the opinion that there was "much excellent sense in his procedure. The injury itself was washed and kept under a clean bandage. . . . Sir Kenelm was quite aware of the public appetite for hocus pocus, and surely there was a touch of anticipatory Christian Science and Coué in his idea of keeping the patient's mind off the trouble and giving him this harmless amusement in the open air. . . . The injury was left to the curative progress of Nature. This theory of treating not the wound but the weapon might well be meditated."

Anne MacDonell (7) characterized Digby as "a professional unpaid physician who carried on a frequently interrupted practice." Surely not as a source of revenue, but as one manifestation of a diverse range of interests. Amateur actually he was, for his researches into the medical sphere were conceived only through a natural desire for knowledge, and to capitalize on his attainments was far from his motive. It would seem more appropriate, viewing him from the vantage point of time, to rate him as an amateur physician, and not, as did those of his day, berate him as a deliberate trifler in science.

II.

In common parlance *The Closet of Sir Kenelm Digby Opened* (7) is a cookbook, comprising as it does a number of recipes for the concocting of "Metheglin, Sider, Cherry-wine, etc., together with Excellent Directions for Cookery, as also for Preserving, Conserving, Candying, etc." The book contains several items of medical interest as illustrative of the dietetics of Digby:

Metheglin, a "sticky, sweet sort of beer" (8), is granted especial attention, being a "very wholsom Drink . . . esteemed to be an excellent Pectoral, good against Consumption, Phthisick, and Asthma; it is cleansing & diuretick, good against the Stone & Gravel; it is restorative and strengthening; it comforts and strengthens the Noble Parts, & affords good nourishment, being made Use of by the Healthy, as well as by the Sick."

A typical example of this marvellous species of drink is "Sir Thomas Gower's Metheglin for Health," in which are found sweetbriar leaves, sweet-marjoram, rosemary, thyme, marigold, borrage, bugloss, sage, spices, and honey. Its beneficent action was directed against "Consumption, Stone, Gravel, Weak-sight, and many more things."

"Mr. Pierce's Excellent White Metheglin," "a great Balsam and Strengthener of the *Viscera,*" is

also advantageous against coughs and colds and consumptions. Other valuable members of this class are, as designated: "An Excellent Way to Make Metheglin, Called the Liquor of Life," and "A Metheglin for the Colick and Stone of My Lady Stuart."

Meathe was also a much used beverage, one particular brand of which a Burgomaster of Antwerpe indulged in for many years, "and though he were an old man, he was of extraordinary vigor in every way, and had every year a child, had always a great appetite, and good digestion; and yet was not fat." Another enticing "Meathe Good for the Liver and Lungs" was to be taken "every morning a good draught of it, and at five in the afternoone."

An interesting glimpse at one habit of the discoverer of the circulation of the blood is presented in the form of "Dr. Harvey's Water-Cider, Wherof He Used To Drink Much, Making It His Ordinary Drink."

Recipes of many soups and broths are listed, with a view towards sick and convalescent persons. One instance is a "Grewel of Oatmeal and Rice," which "Dr. Pridion ordered my Lord Cornwallis for his chief diet in his looseness."

Evelyn records that "Digby advised me to try and digest a little better, and gave me a water which he said was only raine water of the autumnal equinox exceedingly rectified, and smelt like *aqua fortis*."

"An Approved Remedy For Biting of a Mad Dog" has a varied formula as well as a familiar addendum:

"Take a quart of Ale, and a Dram of Treacle, a handful of Rue, and a spoonful of Shavings or Filings of Tin. Boil all these together, till half be consumed. Take of this two spoonfuls in the morning, and at night cold. It is excellent for *Man or Beast*."

One naturally expects to run upon some sort of Elixir of Life, and a close approach is made in the "Aqua Mirabilis," which contains such ingredients as cubebs, gallingale, cardamus, mellilot-flowers, cloves, mace, ginger, cinnamon, juice of celandine, spearmint, balm, flower of cowslip, rosemary, borage, bugloss, marigold, sack, angelica and red-rose water, and sugar.

Its efficacy? It "preserveth the Lungs without grievances and helpeth them; being wounded, it suffereth the Blood not to putrifie, but multiplieth the same. This water suffereth not the heart to burn, nor melancholy, nor the Spleen to be lifted up above Nature; it expelleth the Rheum, preserveth the Stomach, conserveth Youth, procureth a good Colour; it preserveth Memory, it destroyeth the Palsie; If this be given to one dying, a spoonful of it reviveth him."

"An observant scholar who dabbled in medicine" (3), posterity does not allow Sir Kenelm Digby to be forgotten. And the medical profession can well be proud to accept as one of its own this selfmade, manysided, resourceful amateur physician.

Contributors to the Science of Medicine

Victor Horsley

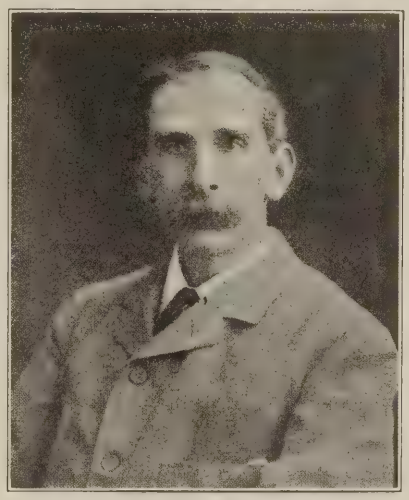
Victor Horsley of London and William Macewen of Glasgow were the two pioneers of brain surgery in Great Britain. Horsley died a martyr to duty and to love of humanity in the burning heat of Mesopotamia at the comparatively early age of fifty-nine. Macewen lived to the allotted age of three score years and ten and died in his bed.

Victor Horsley was descended from a family of artists on both sides. He was son of John Callcott Horsley the artist, and a grandson of William Horsley the musician. William Horsley married a daughter of John Wall Callcott, the musician, brother of Augustus Callcott, the artist. One of William Horsley's daughters married Isambard Brunel, the designer of the Thames Embankment and the Great Eastern Steamship; another daughter married Dr. Seth Thompson; another, Miss Sophy Horsley, was a great pianist and a friend of Mendelssohn; he dedicated some of his works to her. Victor Horsley's mother was a sister of Sir Francis Seymour Haden, the surgeon and artist, who was founder and first president of the Royal Society of Painter-Etchers.

Victor was born on April 14, 1857. He was brought up amid lovely surroundings in a delightful manor house near Cranbrook, Kent. Stephen Paget in his *Life of Horsley,* says that it would be a waste of time to decide what in Victor was Horsley and what was Haden. He got his good looks from his father and both families were represented in his

hands. He did well at school in classics and French but although fond of games did not shine in them. In January, 1874, he matriculated at the University of London and in July, 1875, he passed his preliminary scientific examination, and got a college gold medal for anatomy. The next three years, from October, 1875, to July, 1878, were given to anatomy and physiology. He had Ellis and Thane Burdon Sanderson and Schäfer for teachers. At the end of the summer session 1878, he got the Filleter Exhibition in Pathological Anatomy. In August, he passed the first examination for the degree of Bachelor of Medicine of the University of London; he was in the first class in both subjects, anatomy and physiology, and he gained the gold medal for anatomy.

In 1878 he clerked and dressed in the wards and out-patient department of University College Hospital and attended lectures, postmortem examinations, operations and so on. In 1879 Horsley, who was an excellent artist, made two of the drawings for Bastian's books published in 1880, *The Brain as an Organ of the Mind* and in 1880, in the April number of *Brain,* Bastian and he published a paper on the arrest of the development in the left upper limb, in association with an extremely small right ascending parietal convolution. The notes and drawings of this case had been made by Horsley in 1879. In 1880 Horsley and F. W. Mott were occupied for seven months, off and on, with the subject of bacteriology. They published their results in the *Journal of Physiology,* 1882, in a paper on the existence of bacteria or their antecedents in healthy tissue. Mott, who is still alive, and Horsley while yet students were doing work far in advance of their contemporaries. Horsley was at that time teaching, experimenting and publishing the results of his observations.



SIR VICTOR HORSLEY
(From Garrison's *History of Medicine.*)

In November 1880 he passed the final examination for membership in the Royal College of Surgeons and soon after became house surgeon of University College Hospital. In the summer of 1881, he took the degrees of Bachelor of Medicine and Bachelor of Surgery of the University of London. The gold medal in surgery was awarded to him with a university scholarship. At the end of 1881 he went to Berlin and Leipzig. He lived in Berlin with relatives of Mendelssohn.

During 1882-4, Horsley was surgical registrar to University College Hospital and in the same year was also appointed assistant professor of pathology. During this time he was writing and in July of that year was making some drawings for the ninth edition of *Quain's Anatomy.* In 1883 he became a Fellow of the Royal College of Surgeons.

In 1884, at the age of twenty-seven, he began to work with Professor Schäfer and Dr. C. G. Beevor and was appointed superintendent of the Brown Institution, London. This institution was founded for the study of comparative pathology, or in the words of its founder, Mr. Thomas Brown of Dublin, "for the founding, establishing, and upholding an institution for investigating, studying, and, without charge beyond immediate expenses, endeavoring to cure maladies, distempers and injuries, any quadrupeds or birds useful to man may be found subject to." The superintendents have been Burdon Sanderson, Greenfield, Roy, Horsley, Sherrington, Rose, Bradford and Brodie. The present superintendent is Mr. Frederick William Twort.

Horsley was superintendent for six years and in his time a company of men worked there. In his own share of the work Horsley followed three main lines of research: 1, the localization of function in the brain, and the pathology of epilepsy and canine chorea; 2, the thyroid gland, with special reference to myxedema and cretinism; 3, the protective treatment against rabies.

So far as the discovery of a successful treatment of myxedema is concerned it came not from one line of study but from many. Horsley does not stand alone. But it was he who founded in Great Britain the modern study of the thyroid gland and it was he who first in his own country suggested a rational method of treatment.

With regard to rabies Horsley was Pasteur's chief representative and interpreter in Great Britain. As for localization and function in the brain he did some very notable pioneer work and although it has been modified or corrected here and there, it constitutes a very memorable achievement in science. In 1885, he became assistant surgeon to University College Hospital and in 1886 surgeon to the National Hospital for the Paralyzed and Epileptic, Queen Square, London; and professor of pathology at University College. He was assistant surgeon to University College Hospital from 1885 to 1893; full surgeon from 1893 to 1900 and a surgeon in charge of hospital beds from 1900 to 1906; he then retired and was made consulting surgeon. In 1886 the Neurological Society was founded. Hughlings Jackson was its first president and Horsley was one of the original members.

In 1886, as said before, he was appointed surgeon to the National Hospital for the Paralyzed and Epileptic, Queen Square. It is not the only hospital of its kind in London but it was the oldest, the largest, the richest and the best. It was known far and wide for its work and teaching. Horsley may be said to have revolutionized the surgery there. As Stephen Paget says truly, fifty years ago and less than fifty years, the rules for operating on the head were those which Ambroise Paré had taught and followed in the sixteenth century.

The first real brain surgery done in Great Britain was done in 1876 by Macewen in Glasgow, but we can count on our fingers the cases of modern brain surgery recorded in surgical literature up to the time of Horsley's appointment to Queen Square. He had

prepared himself thoroughly for the task. He had been engaged for two years, in his work with Schäfer and with Beevor, over brain surgery on monkeys; he had done more than a hundred of these operations on animals. He knew what he had to do, he did not need to experiment on man, he had done so already on monkeys, and especially he had acquired familiarity with brain surgery under the very conditions he would find at Queen Square; the conditions of operating with neither wound nor scar nor depressed fracture to guide him, nor anything else except the facts of cerebral localization.

His first operation was on a young Scotsman of twenty-two who had had a brain injury at the age of fifteen and who had had fits of extraordinary frequency since that time. He had 2,570 fits during his first thirteen days in hospital. The diagnosis was scar involving the hinder end of the superior frontal sulcus. Horsley removed the scar in the brain, and the surrounding brain substance to the depth of two centimetres. The wound healed well; the mental condition was improved; and the fits ceased.

Stephen Paget tells an amusing tale in connection with this operation. The physicians watched it with intense interest and when it was over Hughlings Jackson let himself enjoy the relaxation of the strained mind. He beckoned to Ferrier: "Awful, perfectly awful," he said. Ferrier was shocked; the operation had seemed to him faultless. Again Hughlings Jackson murmured that an awful mistake had been made. "Here's the first operation of this kind that we have ever had at the hospital; the patient is a Scotsman. We had a chance of getting a joke into his head, and we failed to take advantage of it."

In August at the annual meeting of the British Medical Association in Brighton, Horsley read a short paper on brain surgery. He had done three operations at Queen Square, he described them, and showed the patients; excision of scar; removal of tuberculous tumor and of the thumb area; removal of splinter of bone and surrounding cyst. Among those who discussed the paper and congratulated him were Charcot, Hughlings Jackson and Erichsen.

In April, 1887, he published in the *International Journal of Medical Sciences* his first contribution to American literature; an essay on the accurate use of such lines and angles of measurement as give the relations between the surface of the skull and the surface of the brain, and enable the surgeon to visualize the motor area of the brain in its exact position under the skull. On June 9, 1887, he removed a tumor from the spinal cord; the first operation of its kind ever done.

On October 4, 1887, Horsley was married to Miss Bramwell and in 1891 settled in a house at 25 Cavendish Square. In 1891, too, he gave the Croonian Lecture; Horsley's Fullerian Lectures and with Sims Woodhead as editor founded the *Journal of Pathology*. He was also appointed vice-dean of the Medical Faculty of University College.

In 1894 the Royal Society awarded to him one of its gold medals and the University of Halle, at its bicentenary festival, gave him the honorary degree of doctor of medicine. In 1893 he made a long series of experiments with Dr. S. P. Kramer, of Cincinnati, and on March 15, 1894, at a meeting of the Royal Society, a paper by Kramer and Horsley was read. In 1897 he was invited to give the Cartwright Lectures in New York but could not accept the invitation. During all those years he was continually writing and reading scientific papers and reports of operations. However, from 1899 on he was so hard at work at practice and professional politics that it was impossible for even a man of his boundless energy and capacity for work to give much time to the writing of papers. By 1904 professional politics were less pressing and he embarked again on writing with renewed vigor.

Horsley was an extraordinarily versatile man and endowed with personality not untinged with aggressiveness. He was an impetuous fighter for a cause which he thought right and he belabored his opponents with vehemence. For example, he was a strong believed in total abstinence and his diatribes against the use of tobacco were almost as unrestrained in language although based on scientific principles as the celebrated *Counterblaste* of James the First. By these means he made many enemies and seemed to infuse into discussions in which he took part more than a trace of bitterness. He was intolerant of views that were in conflict with those that he held. But he was transparently honest and his intentions were of the best and it may also be added that in his opinions concerning alcohol he was before his time. Scientific men on the whole are now in conformity with his convictions. Horsley was a keen archeologist and knew his subject by observation and not from books. In 1902 he received the honor of knighthood, an honor indeed not at all in keeping with his great and deserved reputation. Many British surgeons and physicians with scarcely a tithe of his ability have received far greater honors.

Horsley was a name known and honored in Europe and America. He was one of the few outstanding figures of the medical world in his generation, and it may be said that he received honors from almost every university in Europe. He was greatly interested in the question of national deterioration and gave evidence before the Committee on Physical Deterioration. Although he was interested in all aspects of this question he was limited to discuss but one phase of it, the venereal diseases and the measures to be taken against them. He urged that a commission be appointed to inquire into their prevalence and pointed out that statistics founded on hospital practice were useless, as also were statistics based on death certificates. He was in favor of compulsory notification. In 1906 he gave up his position at University College Hospital and his professorship of surgery at University College. He had completed twenty years at Queen Square and in his Toronto address on surgery at the meeting there of the British Medical Association he reviewed what he had learned in all that time.

It has been said that he would have done much more for science if he had steered clear of politics, but Paget thinks that there is very little truth in that saying. His chief discoveries in physiology and surgery were made in the wonderful years between 1884 and 1900 when politics concerned him little. Also, the output of his work for science, which always varied, never stopped; it went right on up to the time of the war. He spoke and wrote on almost every angle of nervous function. In 1910 he rushed into

public life with absolutely unrestrained ardor. He was a radical of the radicals and in December election, the general elections were on at the time, he stood as candidate for the University of London. He is said to have made up his mind long before 1910 that when he was sixty he would retire from practice and enter Parliament. He failed at the general election and never had the opportunity to win success out of failure.

On January 19, 1911, the Lannelongue Prize was given to him. It had just been instituted by Professor Lannelongue, of Paris; a gold medal and 5,000 francs, for the surgeon who in the previous ten years shall have done most for the advancement of surgery; to be awarded, once in five years, by a committee of surgeons, representatives of many nations, Great Britain, and Ireland; the United States and Canada; South America; Japan and China; Italy, Spain, Portugal and Mexico; Scandinavia and Holland; Belgium; Germany; Austria and the Balkan States.

Apropos of this unexampled honor Lady Horsley wrote to a friend, "Victor has been awarded the Lannelongue prize, for the greatest advance in surgery in the last ten years; and goes to Paris to receive a gold medal and a douceur of £200. And a grateful patient in Australia has sent us a white kangaroo! Rings at the bell, therefore, make us extremely nervous, and at the first approach of a railway cart I prepare myself for instant flight." He and Lady Horsley were ardent supporters of the female suffrage movement.

Horsley was essentially democratic and used all his influence to democratize the British Medical Association and the Royal College of Surgeons. His efforts in this direction were of little avail at least so far as the college was concerned. He spent much of his time in fighting against alcohol. It was the passion of his life. He was a fine speaker and model lecturer and used as well his unrivalled knowledge of science and his wide experience of practice.

But his remarkable powers of tongue which were scathing and pen which was pungent made him feared by the members of his own profession and he was quietly kept out of one thing and another by narrow minded cliques. Not only his own profession but the professional politicians were afraid of his honesty and great ability and he was ignored, really a great compliment to him. Moreover, his unpopularity extended to his practice. Medical men would not send their patients to him and some patients were so adverse to his politics that they preferred another surgeon.

And then the war came. Two of his sons joined at once and in May, 1915, the General Hospital to which he was attached was ordered to Egypt. On March 25, 1916, he went to India and in April was in Mesopotamia; he died of heat stroke and overwork at Amarah on July 16, 1916. The shade temperature in Mesopotamia then was 110° and the atmosphere humid. Mr. Martin Swayne in his book *Mesopotamia* describes the funeral: "Shortly after we left Amarah, the news came that Sir Victor Horsley had died. It was in a season of extreme heat, when death comes suddenly in many forms. Eighty officers attended his funeral. He had a coffin. Wood was precious in Amarah. There were some other bodies sewn up in blankets. A long dusty march of a mile to the cemetery, a shallow earth grave, a brief ceremony, the same for all, and a weary tramp home in the sun; that was the final picture. There is one more detail to add, and that is the lovely playing of the 'Last Post' over the graves."

Victor Horsley was not only a physiologist and surgeon of international fame, an original thinker not afraid to put his views into practice, a pioneer in every respect and possibly the greatest man of the medical world of his time, but he was a great moral force. He stood unflinchingly for clean living and preached his gospel undeterred by the fact that by so doing he incurred unpopularity and even odium among some. He kept his ideals and acted up to them, indeed sacrificed himself for them, but his name will live.

Cancer in History and Art.—Dr. Henry Meige, professor of anatomy at the School of Fine Arts, gave recently at the French-Anglo-American League against Cancer a very interesting lecture on cancer in history and art.

Although we have very little information on the pathological condition of celebrated men of antiquity, a search in modern times gives more fruit. It is a curious fact that no king of France for ten centuries was unafflicted with cancer. Only two queens, Marie de Medici and Anne of Austria, contracted it, one having probably had cancer of the stomach, the other without doubt cancer of the breast. But, although royalty dwelt for a thousand years under the shadow of this terrible malady, it apparently disappeared with the founding of the Empire, with one exception. Napoleon I undoubtedly died of a cancerous ulcer of the small end of the stomach, complicated with an hepatic affection, contracted perhaps at St. Helena.

Rare in history, cancer is still more rare in art. No artistic reproduction of any kind exists which is incontestably related to it.—*Æsculape.*

The Psychosis of Villon.—In the study that he has published, the *Psychose de Villon,* M. R. Yves Plessy inveighs against the "whitewashing" and concealments prevalent of the real character of Villon. He considers him the best poet of his time; that is an irrelevant matter, but what of the man himself? Bully, murderer, picker of locks, swindler, habitual sneak thief. Was he mad? Perhaps not, but an overwhelming heredity led the way to his psychosis. He showed in his characteristics the stigmata of degeneracy; the weakness of his constitution was balanced by his precocious mental keenness; he was unstable, unmoral. The murder of the monk Sermaise, whom he killed in a brawl, was purely impulsive. We must remember, however, that he was provoked and that the dagger of Sermaise was drawn first. This murder was the chief cause of the misfortunes of Villon, and threw him into the underworld. It did not destroy his talent, for he was always able to apply it to the situation in hand. . . . In short, M. Yves Plessy wishes only to correct a misunderstanding on the part of those writers who have believed that they should endow Villon with the flower of all the domestic virtues.—*Translated from Æsculape.*

Editorial Articles

TUBERCULOSIS AND THE TEETH

At one time the dental pulps were supposed by many physicians to be the portal of entry of the Bacillus tuberculosis into the human body. This is not surprising when the association of diseased and defective teeth with tuberculosis is remembered. In fact, it is surprising how very frequently the tuberculous have bad teeth. Tuberculosis seldom develops in well nourished people. Tuberculous people are seldom well nourished, hence there is a vicious circle of bad teeth, bad nourishment. From this it follows that one of the best means of preventing tuberculosis is to insure a proper degree of nourishment at all ages, but especially among growing children.

The prime prerequisite for this is sound teeth and healthy gums, because the person having these is more apt to eat with relish a certain amount of tough, fibrous, bulky vegetables, fruit and meat. This is a dietary calculated to promote health, increase nourishment and produce a resistance to tuberculosis. On the other hand, such a dietary is avoided by the person with sensitive teeth or gums and replaced by a soft, badly balanced diet provocative of indigestion and malnutrition.

These seem like trite and threadbare statements, yet they cannot be repeated too often and every physician who makes a physical examination of a patient should note the condition of the teeth and if it is not good, refer the patient to a dentist after explaining carefully the vital necessity of putting his mouth in a healthy condition and so maintaining it. While it is true that most cases of tuberculosis are contracted in childhood, it should be borne in mind that it is during adolescence and adult life that the disease most frequently manifests itself. Good teeth and good nourishment constitute our strongest single weapon against tuberculosis.

PRECANCEROUS STATES

In the efforts being made in many countries to discover the cause of cancer, the importance of prevention and effective treatment seems to be somewhat overlooked. The discovery of the cause, and it appears more than likely that there are several agents or factors concerned in its causation and that it is of multiplex pathology, does not signify that curative or remedial treatment is immediately at hand. The history of the discoveries of the causes of disease tend to negative this conclusion. If, for instance, a germ of cancer is found, it does not necessarily mean that it will be possible to treat the disease successfully but rather that it may be possible to prevent it from developing. It would be an immense advance in this direction if precancerous states could be correctly diagnosed as it would or might establish a more definite means of preventing the proliferation of the cancer cell.

At a meeting of the Surgical Section of the Royal Society of Medicine in London on November 14, 1925, a discussion took place on precancerous states. Among the speakers Dr. E. Shaw said that he had no doubt of the existence of a precancerous state. The two main conditions to be considered under the term were chronic inflammations and simple new growths. In his opinion a breast affected with chronic inflammation was in a precancerous state, as also were many skin and mucous papillomata showing invasion of the deeper tissues by superficial cells. In the cervix evidence of development of carcinoma or chronic inflammation was provided by the transition from squamous to columnar and the appearance of definitely malignant groups of squamous cells deep in the muscle.

Dr. R. M. Livingston pointed out that a chemical contrast between acute and chronic inflammation had been determined. The reaction of the tissues in chronic inflammations was invariably acid while in acute inflammations it was alkaline. Pyogenic microorganisms at work produced acid which was oxidized by the action of the tissues in acute conditions. It might be that this acid secretion rendered tissues more vulnerable to cancer. Dr. Gye's work bore out this hypothesis. On the whole the discussion did not tend to show that many precancerous conditions can be detected.

In this connection a paper contributed by Dr. J. Shaw Mackenzie to the *Journal of Tropical Hygiene* is of great interest. This investigator has been working for many years in the laboratories of King's College, London, and has been greatly impressed by the varying degree of resistance which the human subject offers to the invasion by cancer. He points out that a certain number of mice possessing a natural immunity are negative to tumor inoculation and he thinks it not unreasonable to presume that such an immunity may be present more or less in human beings. Therefore, he argues, it is most important to discover if any differences exist between the blood of cancerous and noncancerous subjects and whether the blood can be so treated in cancer patients as to increase the resistance of the tissues to the disease.

Dr. Shaw Mackenzie has found that the blood of cancer patients is deficient in lipase, the fat splitting

ferment of the pancreas, and that the resistance to cancer tends to rise and fall in proportion to the amount of lipase in the blood. He has further shown that the fat splitting lipase is separable into two parts, an activating coenzyme and an inactive one. The two are active in conjunction but each is inactive by itself. He holds that this finding is in keeping with Dr. Gye's finding that the cancer tumor contains a specific factor plus a virus, the cooperation of both being essential for the production of cancer tissue. Thus Dr. Shaw Mackenzie makes use of the lipolytic action of the blood as a means of diagnosing the presence or otherwise of cancer. A normal reaction suggests strongly its absence.

It logically follows the findings of Dr. Shaw Mackenzie that if the presence of cancer is associated with defective enzyme action in the tissues and in particular with tissue lipolysis, treatment must be directed to providing the tissues with lipase activators such as pancreatic coenzyme. Moreover, it is claimed that successful results have been obtained along these lines. If the findings of Dr. Shaw Mackenzie that he can diagnose precancerous states even with fair degree of accuracy are confirmed, a great advance in the prevention of cancer will have been made.

WALKING THE FLOOR

"He walked the floor all night." So the biographer of Lincoln tells us in narrating times of special stress, and walking the floor for shorter periods at least is common practice with many lesser persons in like condition of anxiety or indecision. So the adult, and even the infant in its times of ill adjustment of "internal to external relations" seems to profit by being perambulated rhythmically to and fro even in the small hours of the night. Nor is this business of walking the floor confined to humans. We come naturally by it, for animals in like situation, confined within walls (as the human is confined in more complicated fashion by abstract barriers which he knows not how to surmount or in what way to surmount) paces back and forth, back and forth, for much of his day and much of his year.

Walking the floor is a natural expression of superfluous energy—of having nothing else to do, as in the animal born in captivity, or of not knowing what else to do, in the case of the vigorous perplexed human.

The human race is characterized by having a superabundance of nervous energy, and, unfortunately, living is not only more complex and perplexing than ever, but old means of letting loose that energy are being closed up more and more. Walking the floor to slow rhythm is not sufficient for the surcharged battery of the modern—he must dance the floor at wild speed and that with extraordinary contortions, even at the time he is taking in more energy—at meal time, or he rushes into athletics which he carries to the limit. He even adds energy to his own, and explodes gasoline in the nervous system of his automobile while he scurries at breakneck (for the person in the way and often for himself) speed over the country.

These surcharged nervous systems, when their discharges are in the right direction, are very excellent things, but the person who naturally plods back and forth through a night is a much more reliable and effective agent in the business of life than one who seeks outlet in fitful spasms of jazzmanian movements or in competitive sports. No matter what the calling, the person capable of splitting rails all day has been most capable of the highest type of work in his special line. Our Goethes, Brownings, Beethovens, Michelangelos, Sargents, Listers, and Oslers, have not been flash-in-the-pan people; they have been nervous—highly nervous—but not merely neurotic.

The disappearance of manual labor and our increasing leisure make it more and more imperative that means of healthful expression of energy be found, not only for young people but for adults, and that the upbuilding of capacious and well controlled nervous systems be a special feature of all child culture. We need to take this into consideration in our educational systems into which the young of the species are driven against their wills. Anything to which we are so exposed is not likely to be altogether beneficial to health unless planned and managed with the utmost wisdom. Education has always been an experiment, and it is a question whether it is altogether a successful experiment from the point of view of producing a well ordered nervous system, although it is just this that it ought to aim to secure. That the school is adapting itself to the need for nervous outflow—to selfexpression—is a sign that it is moving in the right direction. It is doing much to further the general hygiene of youth, it gives more opportunity to play for all and less attention to interscholastic athletics, and, on the whole, it is living up to its light when it is considered that it arose in an era of asceticism and had its early dwelling in the cloister. It is still, however, an indoor affair and mind is largely considered as something distinct from body.

It is in the more important periods, before school days arrive, that the nervous system is planned and the foundations laid and it is in the hygiene of this period for which the nurse, family physician, the obstetrician and the pediatrist are in large degree responsible, that most can be done. After this period

the guiding of superfluous energy into best channels of expression becomes of growing importance to the individual, to the home and to the community.

PSYCHOLOGY AND FICTION

Novels of recent years have teemed with psychological interest. Dostoievsky, Marcel Proust, James Joyce, D. H. Lawrence, some women and the rest have analyzed human motives and subjected to a minute dissection the unconscious mind to their heart's content and to the delight of some of their more sophisticated readers. And now these probers into the mysteries of the human ego have themselves undergone at the hand of a psychologist an intensive analysis.

Dr. Joseph Collins in *The Doctor Looks at Literature,* and to a lesser extent in *The Doctor Looks at Biography,* has attempted to explain to the unsophisticated reading public unversed in psychological lore the meaning of the seemingly prurient fiction so prevalent in these latter days.

In considering critically certain writers of fiction from the point of view of psychology Dr. Collins has succeeded more than passing well.

In the *Ulysses* of James Joyce, of course, he sees more than the chaotic outpouring of a depraved mind and attributes to him the gift of genius run riot. To Feodor Dostoievsky he pays unstinted homage stating that in his opinion posterity will link his name with Pushkin and Tolstoi as the three great writers of their times. Dostoievsky describes many of the nervous and mental disorders, as mania and depression, the psychoneuroses, hysteria, obsessive states, epilepsy, moral insanity, and that mysterious mental and moral constitution termed degeneracy with a masterly delineation. Moreover, there is no evidence or indication that he had access to books on these subjects so that it may be inferred that he evolved this knowledge from his inner consciousness aided by observation and quickened by the fact that he was an epileptic himself and that one of his parents appeared to be mentally diseased while the other was physically and perhaps mentally diseased as well. Also his upbringing and environment tended to foster any neurotic qualities which may have been inherent.

The author gives an interesting dissertation on epilepsy and points out that Dostoievsky had the epileptic auræ and equivalents in an unusual way and with extraordinary intensity, and the narration of them as they were displayed in the different characters of his creation who were afflicted with epilepsy is an important part of his books.

It is a somewhat curious point that although the alienists of the day depict Dostoievsky as an acute psychologist he disclaimed this title and declared that he was only a realist in the highest sense of the word, that is, he made a pen picture of all the soul's depths, which he went on to say he regarded as the only true realism. Dostoievsky was a mystic idealist who represented the essence of the Russian soul through his unconscious to his conscious mind and then expressed it. That he did this in a disorderly way was because he was abnormal and also because it is not a part of the typical Russian mental or intellectual make up to act, speak, or write logically and clearly.

Dr. Collins hails Marcel Proust as the greatest psychological novelist of the day; many other critics both of literature and psychology will think that this estimate of the brilliant erratic French writer is much too high and that in spite of his superior clarity of expression and language he does not compare favorably with the Russian. Other writers of the same school whom the author lauds and at the same time damns with faint praise or is outspokenly critical of the abuse of their literary powers or of the expression of their psychological acumen are Rebecca West, Dorothy Richardson, Katherine Mansfield, Stella Benson, D. H. Lawrence and J. St. Loe Strachey.

One may pardonably wonder what the esteemed precise and perhaps pedantic editor of the *Spectator* and of several biographies of well known people which have made public more of their failings than their virtues is doing *dans ce galère.*

The point which strikes one most forcibly in reading these two last books of Dr. Collins is that in *The Doctor Looks at Literature* at any rate, the great writers analyzed appear to be or to have been diseased men with diseased or, at least, abnormal minds. The chief theme is and was perversions. This is doubtless the feature which makes their writings and doings of paramount psychological interest but it gives one to ponder over Max Nordau's statement that genius was a form of mental aberration and to believe that he had strong grounds for this dictum. By no means the last word has been said on psychology and Dr. Collins's analysis of fiction and psychology and of the writers thereof may aid in elucidating some of the obscure points and some of the hidden crannies of the unconscious mind.

Whatever the reader may think of Dr. Collins's powers of psychological deduction he cannot fail to be impressed by the wide knowledge of literature and especially of biographical literature possessed by him and displayed in his writings. This knowledge is encyclopedic in its range and must have involved much strenuous and meticulously careful reading. He makes few mistakes and misses few features of psychological concern. He is somewhat too dogmatic in his statements and hypercritical but the books referred to are eminently readable as much on account of their human interest as for their literary merits.

Obituary.

SIR JOHN MacALISTER, F.S.A.,

London

Sir John MacAlister died in London on December 1, 1925. He was born in 1856, educated at the High School in Liverpool and was for three years a medical student in the University of Edinburgh. As his health broke down he did not continue in the study of medicine, but became sublibrarian of the Liverpool Library. He exhibited all the characteristics of the good librarian, love of books, love of order and so on, and was presently appointed chief librarian of Leeds Library. He did extraordinarily efficient work in this position and played a leading part in designing the internal structure and arrangements of the new library in Leeds. In 1877 the National Liberal Club of London appointed him librarian but he had held this position for a short time when he was offered the post of librarian and secretary of the Royal Medical and Chirurgical Society. He accepted the offer with pleasure.

When MacAlister took charge, this society had its quarters in a small house near the Middlesex Hospital, the membership was comparatively small and the funds were low.

MacAlister took counsel with Sir Andrew Clark, the leading physician of the day, and with his financial aid obtained a fine house in an excellent locality. Hardly had the society settled in their new house when MacAlister, again supported by Sir Andrew Clark, brought forward a scheme for the amalgamation of the medical societies in London, eighteen or so in number. If Sir Andrew Clark had lived doubtless this scheme would have been carried into effect promptly. Owing to his death it was left in abeyance for a few years.

In 1905 preparations were well advanced and Sir R. Douglas Powell, who was then president of the society, gave the weight of his authority in support of the scheme, which met with the approval of all the members. When this amalgamation plan had come into force, it was found that there were so many members of the combined societies that the house of the Royal Medical Chirurgical Society was not nearly large enough. MacAlister was again the prime mover and by the exercise of tact and suavity, backed by boundless enthusiasm, he not only found a most suitable site for a new building, but contrived to raise sufficient money to erect one in keeping with the dignity and importance of the Royal Society of Medicine, the name given to the amalgamated societies. It is situated at the corner of Winpole Street in the heart of the "doctors'" district of London, Winpole Street being one of the streets in which practically every house contains physicians and surgeons.

This then was the monument Sir John MacAlister raised to himself. When those who knew him look at this building they will not fail to recall the many services he rendered to the medical profession, services unselfishly given, as he was one who never spared himself but thought solely by the cause he loved and for which he worked without stint.

Sir John MacAlister was a fine, handsome man of the Viking build and appearance and with charming Celtic manners. He possessed the Highland gift of imagination, but held in check by shrewd Scotch qualities of organization fortified by incredible industry. The more difficult the task the better he delighted to grapple with it. In addition to building the house of the Royal Society of Medicine with its really magnificent medical library, he largely helped to promote the fellowship of medicine scheme and it may be said was particularly interested in American medicine and never missed the opportunity to praise American medical methods and the energetic way in which medical men of this country got things done. There are many medical visitors to London from America who will remember Sir John MacAlister's genial, pleasing manners and will regret the passing of such a personality.

JUAN GUITERAS, M.D.

Havana, Cuba

The whole medical world suffered a significant loss in the death on October 25th of Dr. Juan Guiteras, Cuban pathologist and hygienist, and former Minister of Health of the Republic Cuba. Dr. Guiteras was born at Matanzas, Cuba, on January 4, 1852. He was educated at La Empresa, Matanzas, and received his medical degree from the University of Pennsylvania in 1873, which also bestowed upon him the degree of Ph.D. He was appointed in the same year resident and visiting physician to the Philadelphia Hospital and retained the position until 1879, when he entered the marine hospital service, where he remained for ten years. He held the professorship of medicine in the Charleston Medical School from 1884 until 1888, and of pathology in the University of Pennsylvania from 1889 to 1899. During the Spanish-American War he served on the staff of General Shafter as yellow fever expert, having served in the capacity of such an expert during all the epidemics since 1881. In 1900 he was appointed professor of general pathology and tropical diseases at the University of Havana, where he remained until 1921. In 1909 he was made Director of Public Health of Cuba and served in that capacity until 1921. From 1921 to 1922 he served as president of the National Board of Health and as secretary of public Health and charities of Cuba.

His great work in yellow fever is too well known to need comment here. He had been a member of the Yellow Fever Commission of the International Health Board since 1916. To mention a few of the outstanding features of his work and career—he discovered the filaria Bancrofti in the United States, and the uncinaria in Cuba. He established the importance of infantile yellow fever in the endemicity of the disease. His written contributions to the study of this scourge of the tropics are some of the most valuable documents that medical science possesses on this subject. He was an authority also on other tropical diseases.

Many American societies made Dr. Guiteras an honorary member of their bodies, among them the American Medical Association, the Association of American Physicians, the College of Physicians of Philadelphia, and the American Society of Tropical Medicine.

School of Tropical Medicine and Hygiene Institute, Calcutta

Travel Notes on India and the Far East

AUGUST SCHACHNER, M.D., F.A.C.S.
Louisville, Ky.

India, whether considered from an ethnological viewpoint, with its teeming masses of humanity sharply divided into almost innumerable casts, or from a religious viewpoint replete with its religions and their countless methods of worship, with a fervor unknown elsewhere in the world, or, from a medical viewpoint with its array of tropical diseases, its practically unchecked waves of plague, cholera, smallpox, and other epidemics, is easily the most interesting and frequently the most trying country that a traveler can select for his investigation.

The Mohammedan tombs in the North are as sublimely beautiful as the Hindu Temples are impressive in the South. Between the two are the gorgeous palaces of the Rajahs and Maharajahs as classical examples of Eastern magnificence, that stand out in bold relief upon a background of Oriental misery; it is indeed a land of extremes.

Travel in the East, as elsewhere, is no longer what it was. To the passport annoyances are added the police surveillance which suggests the growing suspicions of the white man as to the uncertainty of his footing and the uncomfortable premonition that the "rising tide of color" is after all not a mere figure of speech. When the expression of "white arrogance" assumes a sufficiently definite form as to find its way into the British India government report (1924), you begin to realize that the sleeping colossus is turning in his slumbers preparatory to the awakening.

Extravagant estimates as to the annual number of deaths from such diseases as the plague and cholera were not uncommon, originating among members of the Indian Medical Service. There are estimates of as many as a million deaths each from plague and cholera during the course of a year throughout India. This is likely overdrawn but it would be difficult for the government itself to give more than approximately correct figures on their death and birth rates.

The Directors' Public Health Report of the Bombay Presidency published February 9, 1925, yielded the following extract: "The increased mortality over 1922 which was the low record year, from 452,581 deaths to 496,244, was mainly the result of epidemics, plague, cholera, measles and smallpox, which carried off over 50,000 people, or thirty-one and a half times the number in 1922. Influenza as a factor in causing deaths has steadily diminished since 1918, when the estimated number of deaths was 1,041,481. In 1923 less than a thousand deaths were returned as being due to this cause. The number of deaths from cholera was 9,221, against 2,768 in 1922, and 12,886, the average for ten years. During the year there were 33,741 plague deaths, equal to a death rate per thousand of 1.76, or four times the figure for 1922. Dharwar and Belgaum are the chief plague centers for the presidency. In Satara-town practically thirty-one per thousand of the population died of plague. Deaths from smallpox numbered 2,811, as compared with 1,170 in 1922."

These extracts while dealing with conditions in the province of India known as the Bombay Presidency, will afford some basis for an estimate of conditions.

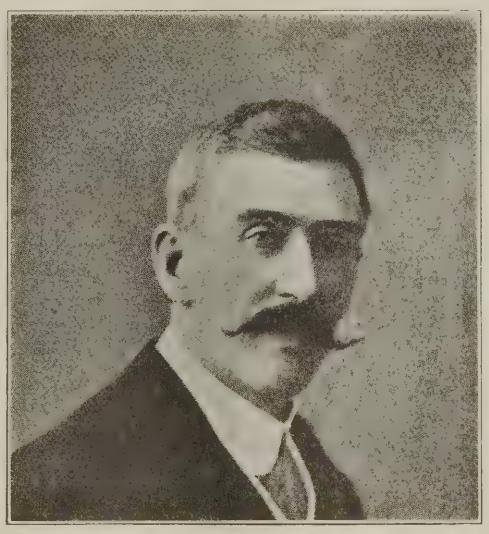
MEDICINE IN INDIA

To those interested in the present and the future practice of medicine in India, it is well to suggest a

review of the significant paper Some Aspects of the Future of Medicine in India, by Major-General Sir Gerald Giffard, K.C.I.E., C.S.I., I.M.S. (Retd.), which appeared in the *Asiatic Review* of January, 1925, and from which the succeeding statements have been derived. Medicine in India is largely a government department, i. e., made up of government servants more or less bound up with the army. To this may be added a growing body of private practitioners and a considerable number of missionaries medical men and women. The public health service, medical college, hospital and research institutes are almost all state supported institutions.

There are three systems of medicine in vogue in India. Western medicine, with its free and open features as becomes any scientific pursuit where the search for truth and progress is predominant.

The unprogressive, decadent and somewhat secret Ayurvedic, or Eastern, or Hindu, and Yunani, or Mohammedan systems. Thirty years ago these systems, which are referred to as "vestigial remnants of medical knowledge of two to two thousand years ago," were about to disappear before the advent of European medicine, but now they are being revived in that a large Ayurvedic school has been founded in Delhi, with smaller ones in the provinces. Not alone were they founded, but they received the personal support of the viceroy and provincial governors, as well as the almost unanimous support of the Indian politicians. Furthermore, the local governments have voted money for the Ayurvedic and Yunani systems and have subsidized their practitioners." It is unfortunate that the three systems cannot meet and expose their points good and bad, with the adoption of the good in each and the rejection of the bad in each. It illustrates the chasm that exists between the Occident and the Orient, and the difficulties of bridging this chasm.



SIR LEONARD ROGERS

"From this it seems that the future medicine in India, if not more or less in conflict, will at least be in a mixed up state. With this as the outlook it is all the more important that Western medicine should be represented in its most effective manner. That the Oriental systems are not brought in comparison with an inferior grade of medicine," which is one of the most effective points which Sir Gerald makes and at the same time leaves the reader somewhat of the opinion that this very thing is not only happening but that British India is somewhat reluctant to make provisions sufficiently liberal to secure an efficient representation of Western medicine.

Such a belief we are afraid will be concurred in by many travelers who are already inclined to express themselves with being more impressed by the "Unpaid debt of Great Britain to India," than any debt which India may be said to owe to Great Britain. Or in other words that the British Indian government does not spend as much of India's producing revenue upon India as it should.

In Calcutta is located the School of Tropical Medicine and Hygiene, in connection with the Carmichael Hospital for Tropical Diseases. It is a splendid institution and a monument to the genius of Sir Leonard Rogers, through whose efforts its existence was accomplished. It is ably conducted by an efficient and enthusiastic head, Lieutenant Colonel J. W. D. Megaw, I.M.S., and supported by an equally enthusiastic and efficient corps of coworkers. The school for tropical medicine should never have been in London, which is as remote from its real field of usefulness as possible, and deferring its existence in India until four years past was equally an error. The importance of this institution to India, and everyone in India, European and Native, is unmistakable. Possibly no other institution does such valuable and necessary work in scientifically directing the public health movements, in training and distributing doctors of public health, in supplying a central bureau to which unusual cases and conditions can be referred for investigation. Lastly, in aiding the advancement of the science of tropical medicine and the study of the partially developed pharmacology of India. Valuable as this institution is, it is obviously in need of funds. In no way can British India better invest its rupees than by providing ample funds for the fullest development of its activities. Since the revenue of this country is an enormous one it would not be unfair to expect more of its revenue to be spent where it is produced. Or since its labors favorably influence all of mankind, it would afford a splendid opportunity for endowment to any philanthropic agency elsewhere.

The commoner tropical diseases are the malarias, plague, cholera, leprosy, beri-beri, kala-azar, uncinariasis, amebic dysentery, filariasis, the various forms of trypanosomiasis, and other protozoal infections, together with the mycotic skin disturbances common to the tropics. Although India is burdened with a generous variety of tropical diseases, it should not be overlooked that her share of the diseases common to the temperate zones unfortunately remained undiminished.

The patients that enter the Carmichael Hospital, as a rule, come not with one disease, or one form of infection, but usually with two or more infections, hence, each case requires individual study to determine the existing infections.

The opinion was expressed that the socalled racial immunity of the native was largely a myth, and, that instead we had an immunity acquired in infancy through exposure to the various epidemics, i. e., the adults to a large extent representing the survival of

Main Entrance to the Medical School Group, Peking Union Medical College

the fittest. In this there is likely an element of reason, but many will contend that there is not enough to justify the complete dismissal of racial immunity.

Through overfeeding, the fondness for sweets, and the Oriental habit of selfindulgence, the rather amusing expression has become current that "an Oriental who has not sugar in his urine by his forty-fifth year is not fashionable." Whether this is the explanation of the prevalence of glycosuria in the Semitic race in the West is a question.

Water as used in the cultivation of rice, their principal food, unfortunately fulfills the ideal breeding conditions for the mosquito. Where the rice paddies do not exist there are enough stagnant pools and other large and small collections of water that will serve as equally favorable substitutes. With the prevalence of the mosquito, the sand fly and other intermediate hosts, and the free and close intermingling of the thousands not alone from one part of a city to another, but from one part of the country to another, so common through their religious pilgrimages, we have the most perfect conditions for the development and the spread of epidemics so common in this country.

Kala-azar, also known as black sickness, dumb-dumb fever, a form of Leishmania, received its first recognition in the early eighties in Assam, the tea district. In the beginning it was confused with certain severe types of malaria, with which it bears some degree of clinical resemblance, until the parasite was discovered by Leishman in 1900. From Assam, it spread to Bengal, Madras, Ceylon, the Dutch East Indies and the other oriental countries. The mortality in Assam, in 1897, has been placed at 18,000. The means of transmission is still unsettled. The diagnosis is confirmed through splenic puncture and the positive finding of the Leishman parasite. It may remain symptomless for some time until its existence becomes manifested through a provocative attack of typhoid or malarial fever. In the year 1923, in the outpatient department of the Carmichael Hospital, there were 1,117 cases in a total attendance of 15,997. A statement of a definite advance in the treatment has been made by this hospital through the introduction of metachlorparaacetylaminophenyl stibiate of sodium, von Heyden, No. 471.

Through publicity many of us have been trained to think of leprosy in connection with the Hawaiian Islands, as if these islands were the centre of this disease instead of merely one of the outposts of the other leper infected parts of the world where the infection is more widely distributed.

The prevalence of this disease in countries like India can be appreciated by the fact that the skin department of the Carmichael Hospital has demonstrated the existence of leprosy in fully fifteen per cent. of the cases applying for the treatment of skin infections. It exists not alone in the partly dressed, barefooted coolie but likewise in the middle class, merchant, official and professional element, in fact, the servant or individual with whom you may be brought in closest contact may be a leper without your or his knowledge of its existence.

In this same hospital it is believed that the diagnosis can be made through clinical signs before it becomes infectious or the bacteriological examinations are positive. The outlook is hopeful in the early diagnosis and treatment. Chaulmoogra and hydnocarpus oils are the favorite remedies. In Sumatra, injections of thymol in olive oil have found favor.

"In cases which do not yield to any single form of treatment we recommend a triple combination, viz., injections of fifty per cent., hydnocarpus esters in pure olive oil, the solution containing also ten per cent. thymol; potassium iodide orally in small doses rising to large doses as long as there is no reaction; the local application of a twenty to thirty per cent. solution of trichloracetic acid in distilled water with a glass rod covered with cotton wool, applications being made at intervals of from seven to fourteen days to all skin lesions." *Carmichael.*

The Punjab became known to ophthalmology through the operative work of Doctor Smith, of the I. M. S., retired, and more generally known as Jalandhar Smith, after his former residency.

He performed the intracapsular operation and according to current reports as much or more cataract surgery was performed here as in any other part of the world. India of old has been associated with plastic surgery through the Indian methods of rhinoplasty. The cutting off of noses and ears was an ancient method of punishment not entirely confined to India, but became generalized somewhat in the Middle Ages. With the abatement of this form of mutilation we have a new disfiguring force through the destructive sequelæ that attend kala-azar. These disfigurements are common to the cheeks and mouth, necessitating the reconstruction of the mouth. As the past gave us an Indian method for the reconstruction of noses the present may give us an Indian method for the reconstruction of mouths.

Terrace and Portico of Anatomy Building, Peking Union Medical College

BURMA

Although a part of the present British Indian Empire, or more correctly speaking an addition thereto is not Indian in any sense. In every way the Burmese differ widely from the Indians. Rangoon, the chief and most accessible city is located on the Rangoon River about thirty-four kilometers from the Bay of Bengal. This swiftly flowing stream, with its numerous Oriental types in their native sampans, afforded an unfailing interest. With the usually added gorgeous sunsets life upon this stream became a pleasant experience notwithstanding the intense solar glare. Rangoon has a population of about 300,000, which is divided, religiously speaking, into about one third Buddhists, one third Hindus, one sixth Mohammedan and the remainder mixed Christians. Ethnologically, the division is more varied, with the men three fourths more numerous than the women, and the predominant strain Mongolian.

The General Hospital, on Commissioners' Road, is one of the best hospitals in the British Indian Empire. It is constructed of brick, built in units, several stories high, which are connected with one another through corridors of several stories that are screened with a strongly constructed screen with an unusually large mesh, merely as a protection against the entrance of bird life, particularly the crows, which are both numerous and aggressive. The air is kept in motion through slow, steadily moving punkahs, driven by electricity. With its cool marble tiling, the splendid facilities for ventilation supplemented by the punkahs, it provides a comfortable type of hospital even though located in a torrid spot.

There are 450 beds and an English nursing staff with a training school for Burmese girls. The nursing curriculum extends over three years with a special course in maternity. The fee for trained nurses that generally prevails throughout India and Burma is five dollars for twelve hour duty. In their surgery chloroform is the anesthetic of choice. Gastro-enterostomy is the operation of election for ulcers.

From Rangoon our course was along the Burmese Coast, to the Island of Penang, where the inhabitants numerically are more than half Chinese; many of these are extremely wealthy and not afraid to display their wealth. This island, and the view from Penang Hill, represents a tropical paradise, of which there are but few equals. From Penang we ferried to the mainland, the Malay Peninsula. Passing through the Malay States to Singapore was like a journey through a gorgeous botanical garden filled with the rarest of tropical vegetation.

Singapore, Colombo and Hong Kong are what an Englishman would call the Clapham Junction of marine traffic, where ships come and go as frequently as trains arrive and depart from a Union Station in a metropolitan centre; and where the people are as varied as the races that inhabit the globe.

JAVA

From Singapore to Java is a sail of less than two days, and to leave Penang and Malay to pass to Java is merely swapping one fairy land for another. The principal hospital of the island is in an outlying quarter of the European part (*Weltevreden*) of Batavia. It is a splendidly constructed hospital, built in sections and connected with one another by covered

passages, paved with highly glazed tiles. The hospital is a one story structure throughout, presumably as an earthquake precaution, and covers such an area that bicycles are used in moving along the passages from one section to another. It has an elastic capacity; in an emergency through the use of the passages it may be expanded to more than a thousand beds. In every detail it is extremely modern and the whole arrangement a distinct credit to the Dutch Colonial Government.

The hospital is in connection with the medical school, where the native students, who number between three and four hundred, are trained for service throughout the numerous Dutch East Indian islands. The curriculum extends over a period of seven years, the last being spent in the hospital.

Hepatic cirrhosis was as common here as in the West, but not dependent as in the West upon the alcoholic intake. Here it is due to the consumption of highly seasoned food which is a craving common to hot countries. Stab wounds and slashes made into the abdomen with short swordlike weapons testify to the frequency and intensity of their quarrels and verify the fact that these weapons are carried for distinctly useful and not ornamental purposes.

The frequency of vesical calculi in the natives of hot regions can be explained upon a basis of the concentrated urine owing to the limited intake of water and the excess of the output through diaphoresis. The calculi in the European is more likely renal in origin. Kala-azar, cholera, plague and leprosy were said to be comparatively rare in Java, as compared with India. Referring to beri-beri, disclosed a difference of opinion as to its causation. The more general view attributes it to the consumption of too highly polished rice through which the rice had lost the water soluble B, or antineuritic vitamine. Others especially in India believe it to be due to the improper storage in damp and hot *godowns* or warehouses. Storage under improper conditions, it is believed, favors the development of a poison in the rice of microbial origin not unlike, it is said, to the development of pellagra through the use of diseased maize.

As India yields the nux vomica so Java the cinchona bark, and for these reasons a large proportion of strychnine comes from India, and during the World War, the world's output of quinine largely if not altogether came from the factory in Bandoeng.

INDO-CHINA

From Colonial Dutch to Colonial French means going from Java to Indo-China. Saigon, the chief city, like Rangoon, is inland a distance of about sixty kilometers from the coast on the Saigon River. This tortuous stream with its low banks reminds one of our own Missouri River that is here today, but that looks as though it may be elsewhere tomorrow. Its numerous and equally tortuous tributaries with their strong tides solve the major part of the local transportation problem. Looking across this flat country one sees the sails of a sloop or a sampan that strangely seemed to be coming through a rice paddie, instead of sailing upon the surface of a hidden river.

The city is distinctive through the miles of shade trees, a species of tamarind, the branches of which form Gothic arches across the streets. It was never made clear as to whether the planting of these trees had for its object the beauty of the city, and the comfort of its citizens, or a more utilitarian purpose of adding to the permanency of the city by insuring it against the encroachments of the river.

One of the two principal hospitals is located within the city. This is mainly for the European population and the military, in fact, it is called *L'Hôpital Militaire*. The other is located a few miles outside of

Class in Carmichael Hospital

the city, and is reserved for the native population. It is called *L'Hôpital Cholon.* Through the courtesy of Dr. Lecomte, *directeur local de LaSante de Cochinchine,* both hospitals became accessible. *L'Hôpital Cholon* afforded some interesting material. This hospital is being gradually rebuilt. The surgical service is under the direction of Dr. Lalung Bonnaire. Spinal analgesia including high injections is practised. Just the reverse of the Militaire, where general anesthetics are employed with ether as the preference. Splenic ruptures, cases of which were shown, are common here owing to their enlargement and friability through tropical infection mainly malarial. The patella fractures were wired and prompt active joint motion insisted upon to prevent stiffness and atrophy. Gastric ulcers were subjected to gastroenterostomy. For several days prior to the operation gastric lavage with an antiseptic solution and after the operation antipneumonic serum were routine procedures in this hospital.

CHINA

Of the hospitals in China space permits only a brief reference to one—the Peking Union Medical College and Hospital. To encounter a replica of the Johns Hopkins Hospital dressed in the most attractive Chinese garb, in this oriental setting, with its cultural background, which the past so richly and distinctively affords, comes to a traveler as indeed a great surprise.

It cost including the land about five million dollars gold, and it requires almost a million dollars annually for the maintenance of both college and hospital. The funds, if not entirely, are mainly derived from the Rockefeller Foundation, and the standards are those of the Johns Hopkins Hospital and University throughout. This institution is incorporated not in China but in New York State.

It serves as a standard where a standard has been sorely needed, it affords the best of opportunities for training Chinese men and women in the medical and

nursing profession, it provides the Chinese with an entirely new viewpoint regarding the Western civilization and lastly, a centre for advice and assistance where formerly this was almost unknown. While the hospital was built in behalf of furthering Chinese interests Europeans are not excluded. We wonder how many of the Europeans can accurately appreciate the immense importance of having such a modern institution within easy reach in a country like China in time of need.

Those in charge of its construction wisely retained the most attractive of the Chinese architectural effects and decorations, in fact, the main entrance we are told represents the palace of a Manchurian prince with but limited variations.

The head of the department of surgery is Dr. Adrian S. Taylor, a native of Alabama, with a Johns Hopkins training.

Seeing the Chinese and Europeans so enthusiastically working together brings home in a forcible manner the internationalism of the sciences and the arts, and makes one regret that this same internationalism which spells the real brotherhood of man cannot be broadly extended to other divisions of human activity and relationship. Much as we clamor for and cling to our nationalism the conclusion is irresistible that in the end, although it will be in the far distant future, we will be obliged to bury our dear nationalism, for until then there will be no real progress of the whole human race such as we pretend that we would like to see and to have seen.

JAPAN

Reaching Japan, via Manchuria and Korea (Chosen) we visited the hospital of the Imperial University of Tokio. Like most Japanese structures it is mainly built of wood, and of one story. You park your shoes at the entrance, receiving the customary check and a pair of sandals. The Germanic influence here as elsewhere is quite perceptible.

SURGICAL CLINIC IN A JAPANESE HOSPITAL

Through the kindness of Professor H. Shihota we attended a surgical clinic that consisted of two appendectomies and one gastric resection. The anesthesia in all was pantopon and scopolamine, supplemented with local infiltration of novocaine. If the three subjects had been cadavers they could have given no more evidence of pain or sensibility than did these patients. In all the hands were tied and a large red cloth fastened over their eyes. The selection of a transverse incision, and the elimination of a general anesthetic in the gastrectomy afforded evidence of the reaction which the Japanese display towards every advance which modern progress affords. The substitution of the transverse for the usual vertical incision except in the median line has so many advantages and has the support of some of the ablest surgical judgment that it is to be regretted that its more general adoption has been so slow. This is, perhaps, an evidence of how habit limits and enslaves the most of us. The continuity of the resection was reestablished by the Billroth I, with an easy and secure restoration. The operation was throughout deliberate and accurate, the blood loss minimum, and the time as short as efficient surgery justifies.

844 Fourth Street.

Letters to the Editor.

A STEP BACK IN MEDICAL EDUCATION

Philadelphia, Pa., *December 10, 1925.*

To the Editor:

On December 9, 1925, the Philadelphia County Medical Society held a "medical education" meeting in the auditorium of the William Penn High School. The drawing card was Dr. William Allen Pusey, of Chicago, former president of the American Medical Association. The speakers included Dr. Charles W. Burr, Dr. David Reisman, Dr. John A. Kolmer and the Hon. William Potter, president of the Board of Trustees of the Jefferson Medical College. The evening was damp and chilly and the auditorium spacious and slightly heated, with the result that there was a small attendance composed chiefly of medical students, nurses and doctors.

The subject announced for discussion, namely, medical education, had attracted me and I hoped to hear something new and elevating in medical pedagogy, but to my great chagrin and disappointment, I sat listening to a tirade against modern high educational requirements made by medical schools both premedically and by curriculum. Such philippic was made by no less an authority than Dr. Pusey, who pleaded for an increase of medical practitioners in the rural districts and blamed the high requirements of medical colleges as responsible for this paucity. The learned professor, who was chairman of the Curriculum Commission on studies standardization for medical students, was of the opinion that too much time is devoted to laboratory subjects to the detriment of clinical subjects. He would materially reduce the number of hours devoted to these basic subjects and abolish research work altogether by students. The premedical requirements in his estimation should be abolished; students taken directly from high schools; admitted to colleges and graduated after four years, three of which should be given to study and the last year spent in internship at a hospital. This, according to Dr. Pusey would solve the shortage of practitioners in the rural districts without resorting to state aid or medical socialism. Dr. Burr, who followed Dr. Pusey, endorsed the statements of his predecessor and praised the old time preceptor, finding fault with the modern intern who considers his patients as "things to be studied" not even as human animals. Some interns, according to Dr. Burr, are at a complete loss without laboratory assistance. Because of this very clinical ignorance the doctor would further reduce premedical and medical studies!

Dr. Reisman pointed out that the country should make the invitation and stay of practitioners more attractive if it desires local doctors.

Dr. Kolmer advocated the granting of a science degree at the completion of the second year of medicine so that those especially inclined to scientific studies would be able to follow a strictly scientific career, as contrasted to the medical practitioners who are to heal the sick.

Mr. William Potter, as a layman in contact for many years with the profession at the Jefferson Medical College, pleaded for the retention of the

family physician against the wave of specialization.

Dr. James M. Anders presented a resolution for the reduction of the present medical students' educational requirements. Finally Dr. C. A. Morgan, president of the Philadelphia County Medical Society, in his genial way made a few closing remarks endorsing the speakers of the evening.

The meeting was adjourned and thus ended a highly pedagogic discussion in which the key note was medical regress to suit the rural district's demands. The impression on me, especially after hearing my former professors, Anders and Morgan, was perfectly demoralizing to say the least. To hear these dynamic teachers who had transformed a good medical under-graduate school into a post-graduate institution in order to meet the growing demands of a higher education, as going on record for poor medical training seemed a most contradictory state of affairs.

Why reduce the medical standard when medical schools deliberately limit the number of students to about one hundred per class? I understand the University of Pennsylvania and the Johns Hopkins University adhere to this limitation. The number of candidates desirous of entering the medical portals would be legion were it possible to be admitted. It is objected that the laboratory facilities are limited and the chairs of these departments advocate a reduction of students. But if the need for the rural district's practitioners is of such impressive demand, would not state aid solve the financial burdens of the medical schools in providing for adequate accommodation for laboratory instruction?

Why reduce the laboratory work so important to just such prospective country physicians who are to depend on this very assistance for diagnosis?

If the present day intern (according to Dr. Burr) is so palpably deficient in clinical understanding, would he by a curtailment of his medical equipment become more proficient? Should we in the present state of civilization in the east adopt ourselves to the demands of the mountains of Kentucky? Dr. Burr wisely remarked that there are many stages of civilization on this Continent as there are states but without definite state lines. Would it be advisable for us to reduce our medical standards and lower ourselves to the level of inferior civilizations? Would it not be better to raise the popular educational standards in our Great Republic and at the same time keep our medical education on a high plane?

Frankly, I do not see the criterion for reduction of medical requirements to meet the shortage of country physicians. The Rockefeller Foundation is correct in attributing this paucity of rural physicians to social and economic conditions. There is a city ward phenomenon familiar to all of us. The urban attractions are strong for the farm hand, the country youth as well as for the ambitious young physician who is also susceptible to human and environmental influences. If the country were made really attractive to the physician both intellectually and financially, more practitioners would flock to the rural sections. But such attraction is dependent upon so many social and economic factors that medical pedagogy is impotent to solve. The same phenomenon is observed abroad and this in my estimation has given much impetus to state medicine.

American Medical Educational standards should at least equal if not surpass the Continental standards in advanced European countries such as Italy, England, Germany and France, in which a collegiate degree is a requisite to the study of medicine, which extends over a period of six years. The medical profession there is highly honored and esteemed. Doctors occupy high positions in the political and intellectual life in their respective countries. America has advanced by leaps and bounds industrially. Great industrial geniuses and experts have arisen. American medicine should keep pace with this developmental achievement. There is no better intellectual force than that constituted by the medical profession, which should not only be represented by a few towering medical intellects but by the aggregate proficiency of its members.

Let us no longer talk of detracting from medical instruction. It is a known fact that European physicians look upon our diplomas with some degree of doubt and not infrequently express or show American tourists or medical delegates their suspicion on American medical preparation. Aside from the chief function of the family physician "to heal the sick, reduce fever, set the fracture, and bring the darling baby into the world without injury to the mother and child," the doctor must impress his patient with his thorough medical equipment. We have already too many doctors whose general education in history, classics and medicine falls below par. The public is catching up to it and not infrequently compares the medical man with his "doc" of the drug store and the "docs" of the various cults. If our great medical men are on the eve of committing themselves to lower medical standards, it is proper that we direct our children to careers giving them more culture and intellectual development.

Leopold Vaccaro, M.D.

News Items.

Herter Lectures.—Dr. B. Brouwer, professor of neurology of the University of Amsterdam, will deliver the annual Herter lectures of Johns Hopkins University, in April.

Medical Films.—The U. S. Public Health Service has prepared films showing the lesions of syphilis and skin diseases simulating syphilis. The films are not for sale, but will be released to state boards of health for the use of medical societies, schools, and hospitals.

Harvey Society Lecture.—Edward B. Wilson, Ph.D., professor of vital statistics of the Harvard School of Public Health, will deliver the fifth Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, February 6th, his subject being Empiricism and Rationalism.

Devoto Prize.—A fund has been collected to found an international prize in the name of Professor L. Devoto, who recently completed twenty-five years of medical teaching in Milan, and who was the founder and director of an occupational disease clinic. The prize will be awarded biennially for the publication contributing the most to the pathology of occupational disease, by the Milan Academy of Sciences.

Scholarship for Surgical Study.—The J. William White scholarship in surgery for foreign graduate study has been established, the award to be made by the trustees of the Mayo Properties Association. The funds were provided by a legacy from Dr. White, who was formerly professor of surgery at the University of Pennsylvania.

Leslie Dana Medal.—Nominations will be received until March 15th by the National Committee for the Prevention of Blindness, for the annual reward of the Leslie Dana Medal. The considerations are special discoveries, social service in the control of eye diseases, research and instruction, or long service in conservation, of vision or the prevention or cure of eye defects.

Graduate Course in Paris.—An international clinic of otorhinolaryngology and faciomaxillary surgery, for graduate instruction, will be held from May 15th to August 12th at the St. Louis Hospital, Paris. The chief of staff will be Dr. Fernand Lemaitre, of Paris, and the associates are Dr. Harold Delf Gillies, of London, Dr. J. Eastman Sheehan, of New York, and Dr. Ferris Smith, of Grand Rapids, Michigan. Americans should make application to Dr. Sheehan, New York.

Civil Service Examination.—Applications for positions as medical officers, of five grades from junior to senior, will be received by the United States Civil Service Commission, Washington, up to June 30th. The appointments will be for vacancies in the Public Health Service, the Coast and Geodetic Survey, the Panama Canal Service, and the Veterans' Bureau. Entrance salaries range from $1,860 to $5,200, with promotions to $2,400 and $6,000.

Applications for position as medical intern (psychiatric) for duty at St. Elizabeth's Hospital, Washington, D. C., and similar vacancies, will be received by the United States Civil Service Commission, Washington, up to June 30th. Graduate medical students or seniors about to be graduated are eligible. The salary at St. Elizabeth's will be $1,860, without allowances.

Midwinter Course in Gastroenterology.—Two additional courses in gastroenterology to meet the increased demand for instruction, have been arranged by Columbia University, to be given at the Vanderbilt Clinic, beginning January 26th; the second series will begin on March 23d. The preliminary course in gastroenterology will be given by Dr. John Leonard Kantor. This is a course of lectures and röntgen ray demonstrations, designed for graduate students of medicine. The lectures are in three groups, the first covering the nature of digestive disorders, diagnostic methods, therapeutic methods, and organic and functional constitutional inferiority; the second group includes lectures on systemic diseases of the digestive tract; and the third group includes the röntgen ray demonstrations. These demonstrations may also be taken without the other lectures. The practical course is under the direction of Dr. Kantor and Dr. Zachary Sagal. The first course, or its equivalent, is a prerequisite. The work consists of clinical and laboratory procedures and diagnostic methods, and each student will have opportunity to observe, assist with, or perform the methods discussed.

Personal.—Dr. H. Brooker Mills, of Philadelphia, announces the removal of his office to the Medical Arts Building, at Sixteenth and Walnut Streets.

Dr. Charlton Wallace has been appointed attending orthopedic surgeon at the Hospital for the Ruptured and Crippled, New York.

Dr. Frank W. Shipman has been appointed health officer, for life, at Mount Vernon, New York. He succeeds the late Dr. William H. Purdy.

Mr. Albert W. Buck, since 1924 acting superintendent of Johns Hopkins Hospital, has been appointed superintendent of the New Haven Hospital, New Haven, Connecticut. Dr. Willard C. Rappleye has resigned from this position to become secretary of the committee on medical education of the Association of American Medical Colleges.

Two new appointments as health officers in the Baltimore City Health Department are Dr. Charles A. Cahn and Dr. Nicholas W. Pinto.

Dr. William H. Pound has been appointed deputy health commissioner of New York.

Dr. Herman Van Horn, formerly on the staff of the Dartmouth Medical School, Dartmouth, New Hampshire, will teach embryology at the Wittenberg College, Wittenberg, Ohio.

Dr. Carey J. Vaux has been appointed director of public health of Pittsburgh, Pennsylvania.

Dr. Willis B. Merrill, of Columbus, Ohio, has been appointed chief physician at the Ohio State Penitentiary.

Dr. Benjamin H. Hager, of the University of Wisconsin Medical School, has resigned to become a member of the staff in urology at the Mayo Clinic.

Dr. J. F. Montague, of New York, addressed the Berkshire County Medical Society in Pittsfield, Mass., on January 14th, his subject being Popular Fallacies Concerning Hemorrhoids.

Dr. John F. Bresnahan, of the James K. Jackson Memorial Hospital, of Miami, is the new superintendent of St. Mark's Hospital, New York. Dr. Jesse L. McElroy, the former superintendent of St. Mark's, is now superintendent of the University of Iowa Hospital, Iowa City.

Dr. John H. Gibbon, president of the American Surgical Association, gave the Hodgen Lecture of the St. Louis Medical Society, on Mobilization in the Treatment of Fractures.

Dr. Archibald K. Benedict, of Sherburne, New York, has been appointed superintendent of the Chenango County Sanitarium, in place of Dr. D. U. Gould, who resigned.

Dr. John J. Lloyd, who has been medical superintendent of the Monroe County Tuberculosis Sanitarium, Rochester, New York, for several years, has resigned in order to devote his time to private practice.

Dr. George H. Ramsey, of the state department of health of Michigan, is spending six months in study at Johns Hopkins University Medical School.

Dr. Thomas Dwight Sloan, formerly medical superintendent of Peking Union Medical College Hospital, Peking, China, will be the new associate director of the Lakeside, Maternity and Babies' Hospitals of Cleveland, with special connection with Lakeside.

Society News and Notes.

The Audubon Medical Society held its first annual dinner at the Hotel Biltmore, New York, on January 21st. The guest of honor at the dinner was Dr. Theodore K. Tuthill, who has been practising in the city for fifty years.

* * *

The Association of Alumni of the College or Physicians and Surgeons of the City of New York held its annual meeting on January 28th. Dinner was followed by an address by Dr. George A. Soper on the subject of Typhoid Mary.

With its exhibit on the history of appendicitis, the library of the New York Academy of Medicine is showing also material on the anatomical art of Leonardo da Vinci.

* * *

The American Academy of Physiotherapy held a special meeting in New York on January 5th.

* * *

Dr. Adolf Meyer, professor of psychiatry at Johns Hopkins University, will deliver a lecture on Individualism and Mental Health at the New York Academy of Medicine, at 4 o'clock on the afternoon of February 9th. On February 16th, at the same hour and at the same place, Dr. C. Macfie Campbell, professor of psychiatry at Harvard Medical School and director of the Boston Psychopathic Hospital, will speak on New Concepts of Mental Health.

* * *

The New York Lecture Bureau has announced for January and February, 1926, a series of interesting lectures by Dr. Israel Weinstein. Dr. Weinstein lectured in January on Lord Lister, Elie Metchnikoff, Charles Laveran and Ronald Ross, Edward Jenner and on various subjects related to medical science. The February lectures will include Robert Koch, Louis Pasteur and Elie Metchnikoff.

Book Reviews

THE FOOT

Diseases and Deformities of the Foot. By John Joseph Nutt, B.L., M.D., F.A.C.S. Second Edition. New York: E. B. Treat & Co., 1925. Pp. 290.

This book is written for the general practitioner and it is decidedly worth while. So many cases of foot weakness and strain come under the general practitioner's care that it is impossible to send all of them to an orthopedist. The first portion of the book is taken up with anatomy and physiology which well covers the question of foot strain, walking, etc. His description of the proper treatment for weak arches is excellent. The reviewer is glad to see that he gives adequate exercises for the development of the plantar ligaments. It is surprising that one could take up the question of deformities of the foot and develop such an interesting, practical work.

MINOR SURGERY

Minor Surgery. By Lionel R. Fifield, F.R.C.S. With 273 Illustrations. New York: Paul B. Hoeber, Inc., 1925. Pp. 431.

It is rare that a book of minor surgery sticks to minor surgery and does not turn to major operative surgery. This little book is well illustrated with charts, diagrams and photographs of apparatus, etc.

In general the author has taken up exceptionally well the minor surgical operations that come to the general practitioner.

If any criticism might be offered it would be that the item of fractures of the long bones does not really come under the classification of minor surgery. Fractures of the femur and humerus are in reality hospital cases, which demand exceptionally good major surgery judgment in order to return the patient to a satisfactory economic position.

We believe that it does not give enough space to treatment of infections of the hand, as these injuries so often lead to stiff hands where the owner is not able to return to a satisfactory economic livelihood. In general, however, this work should prove exceedingly valuable to the general practitioner.

PROTEIN REACTION

Allergy, Hay Fever, Urticaria, and Allied Manifestations of Reaction. By William W. Duke, Ph.B., M.D. With Seventy-Five Illustrations. St. Louis: The C. V. Mosby Co., 1925.

Few subjects are as interesting and, one may add, as baffling as that of the excessive reaction of the organism to protein, whether ingested in the usual way or finding its entrance into the economy parenterally. As the author points out, the evidence of hypersensitivity may be presented in practically every tissue and every organ, and simulate in any locality the manifestations of functional or organic disease.

This particularly important topic has been presented by Duke on the basis of a careful clinical and laboratory study of over five hundred cases and is considered mainly from the viewpoint of the internist. In every case, the minimum routine included a careful and complete medical history and physical examination, uranalysis, study of a blood smear, a quantitative Wassermann test, and radiographs of the teeth. Even this was supplemented, when it seemed desirable, by studies in blood chemistry and metabolism, by radiographs of the nasal sinuses, chest, and other regions, and, of course, by specific tests of protein sensitization, either individual or in groups.

Part I of this uncommonly interesting and very timely work discusses experimental anaphylaxis, serum sickness, bacterial allergy, pollinosis, and reaction to animal and vegetable emanations. The symptoms and diagnosis of the general reaction, as well as the specific diagnosis, are treated at length, and also the specific, nonspecific, and symptomatic treatment. In Part II there is a thorough study of excessive reaction to physical agents, light, heat, cold, mechanical irritation, and, not least important, mental and physical fatigue.

If any criticism were to be offered it would be that the illustrations, particularly those of pollinating plants, are on much too small a scale, and those of the history and physical examination charts are very indistinctly printed as well, so that it is almost impossible, even with the aid of a magnifying glass, to decipher the various headings.

PREVENTIVE MEDICINE

Health Through Prevention and Control of Diseases. By Thomas D. Wood, M.D., College Physican and Adviser in Health Education, Teachers College, Columbia University, and Hugh Grant Rowell, M.D., Physician, Horace Mann Schools, Teachers College, Columbia University. Yonkers-on-Hudson, New York, Chicago: World Book Company, 1925. Pp. vi-122.

The subject of the preservation of health by means of the prevention and control of disease is receiving attention more and more. This book is devoted to the methods available for making the school, which is a prolific source of disease, a health centre. Such methods occupy an important position in the reduction of the mortality of the school age. The plan outlined is intended to aid teachers, school officials, school physicians, and school nurses, as well as parents, so that the latter may coöperate more intelligently with the school authorities.

The exclusion of a child from school after the symptoms of a contagious disease are already developed serves no useful purpose from the viewpoint of community health. The pupil should be excluded from school on the slightest suspicion and not after the diagnosis has been made, when, as a rule, the damage has already been done. This is the keynote of the whole book. The responsibility for the diagnosis of disease is preeminently the domain of the physician, but nevertheless the school principal, teacher, nurse, or doctor may exclude pupils who develop certain well recognized initial symptoms of contagious disease. The readmission of the pupil after convalescence from a contagious disease under certain restrictions is also an important part of the program.

The various aspects of this question are discussed in great detail, giving specific instructions. The contagious diseases, their methods of recognition and prevention, are described, as well as the standards for

exclusion and quarantine. A chapter is devoted to answers in the form of a catechism, to questions that parents may ask, and one to definitions and explanations.

This book fills a long felt want in the field of school hygiene and no school official of either the teaching or school nursing staff should be without it.

INTRAVENOUS THERAPY

Intravenous Therapy. Its Application in the Modern Practice of Medicine. By Walton Forest Dutton, M.D., formerly Medical Director, Polyclinic and Medico-Chirurgical Hospitals, Graduate School of Medicine, University of Pennsylvania. Illustrated with Sixty-four Halftones and Line Engravings, some in Colors. Second Revised and Enlarged Edition. Philadelphia: F. A. Davis Co., 1925.

The appearance of a second edition of Dutton's fine work in a comparatively short time, and with many additions, revisions, and new illustrations, is striking evidence, both of the excellence of this presentation and, if any were needed, of the general interest in this most important branch of therapeutics. Intravenous therapy, as the author points out, includes not only the administration, by hypodermic injection into the venous channels, of the active principles of drugs, or of solutions, physiological or other, but the transfusion of whole or modified blood, as well. The chapters on this topic, to anticipate somewhat, are unusually complete, authoritative, and instructive. Not only are the various transfusion methods detailed clearly and graphically, but the rather involved, but vitally important, matter of the choice of a donor according to groups and blood types is presented in a thoroughly scientific yet practical manner.

The illustrations, particularly those of apparatus and appliances, add materially to the instructiveness of Dutton's volume. It may be mentioned, in this place, that much of the first edition was appropriated without credit by certain commercial firms and unethical physicians. While we all know that imitation is the sincerest form of flattery, the bold and bald "lifting" of an author's "stuff" is calculated to produce emotions far less pleasurable.

CLINICAL ORGANOTHERAPY

Opothérapie Clinique (Organothérapie)—Formulaire. Par Marcel Laemmer. Paris: Masson et Cie, 1925.

In this small volume the author has taken up the somewhat difficult task of classifying the best known and most used organotherapeutic products according to their clinical use and to give a precise manual of prescriptions for these products. He frankly admits in the introduction that this treatise is merely an essay based on the most recent laboratory findings on this subject and proved by extensive clinical use of the various substances.

These substances are divided into extracts as follows: First, endocrine glands, such as thyroid, parathyroid, thymus, pituitary, suprarenal and spleen; second, mixed glands, such as testicles and ovaries, kidneys, liver and pancreas; third, special glands with an external secretion, such as prostate, mammæ, stomach and small intestine, and fourth, tissues, such as brain, spinal cord, heart muscle, lung and lymphatic tissue, bone marrow and bone, muscle and finally placenta.

After discussing some general rules concerning the dose, prescription, and various methods of administration of these products, the author gives in the second part of his treatise the extensive formulary for their applications in various disorders. Most of the prescriptions are accompanied by references to recent literature, dealing with the organotherapy of the ailment under discussion.

The volume represents a most interesting attempt to develop a reliable manual of organotherapeutic prescriptions. Although it would not be possible after a prolonged use to decide the practical value of the work, it may be well recommended to anyone who is interested in this modern and certainly most promising branch of medical science.

NECROPSY FINDINGS

Postmortem Appearances. By Joan M. Ross, M.B., B.S. (Lond.), M.R.C.S., L.R.C.P., Assistant Pathologist to St. Mary's Hospital. With Preface by E. H. Kettle, M.D., Professor of Pathology and Bacteriology, Welsh National School of Medicine, Cardiff. Oxford Medical Publications. London: Humphrey Milford Oxford University Press, 1925. Pp. vii-216.

This is a practical little handbook on necropsy findings, giving in concise form, the chief anatomical changes found in the commoner diseases. It is recommended by the writer of the preface to the general practitioner who does an occasional necropsy, in which case it serves as a guide to what should be looked for. It is also recommended as a guide to the medical student in the necropsy room.

The introductory chapter deals with the subject of death in general and emphasizes the findings that one would expect to encounter under different circumstances, such as asphyxia, syncope, and coma; the signs of death; necropsy technic. The different causes of death are grouped according to other causes than disease (physical and chemical), general metabolic diseases, general infections, and diseases of the various organic systems. A general plan, consisting of the external appearances and the internal appearances (arranged according to the organic systems), is followed throughout the book.

The appendix includes tables of anatomical normals, of the length and weight of the fetus, approximate weight or organs of the newborn, the dates of ossification of the principal bones, and the ages of the eruption of the teeth.

PAPERS BY MR. PAUL

Selected Papers. Surgical and Pathological. By F. T. Paul, D.Sc. Liverpool (Hon. Caus)., London: Baillière, Tindall and Cox, 1925.

This is a remarkable tribute from the Liverpool Medical Institute of Surgeons to Mr. F. T. Paul on his seventy-fifth birthday. It is a collection of papers written by Mr. Paul during his lifetime. Some of the papers were published as early as 1881. He is a man who evidently has been a great thinker and a keen observer. Many of these studies may be read now with profit. Mr. Paul is best known in this country for his treatment of intestinal obstruction with the use of the Paul's Tube. His article on intestinal obstruction is particularly worth reading.

Medicoliterary Notes.

Prof. Joseph Jastrow will deliver two lectures in the extension courses of the Columbia University Institute of Arts and Sciences, one on the Psychology of Superstition, and the other on Fanaticism.

* * *

The last issue of *Mental Hygiene,* the quarterly published by the National Committee for Mental Hygiene, contains a number of articles of unusual interest. Among them are: Individualism and the Organization of Neuropsychiatric Work in the Community, by Dr. Adolf Meyer; A Tentative Program of Cooperation between Psychiatrist and Lawyers, by Sheldon Glueck, Ph.D., LL.M.; Pleasure and Deterioration from Narcotic Addiction, by Dr. Lawrence Kolb; Personality Deviations and Their Relation to the Home, by Sybil Foster, chief social worker of the Habit Clinics of the Women's Municipal League of Boston; The Masculine Side of Occupational Therapy, by Louis J. Haas, director of men's therapeutic occupations at Bloomingdale Hospital: The Rôle of Conferences with Relatives in the Educational Program of a State Psychopathic Hospital, by Dr. Franklin G. Ebaugh, director of the Colorado Psychopathetic Hospital; Syphilis in the Etiology of Mental Deficiency, by Dr. Neil A. Dayton, assistant superintendent of the Wrentham State School; Résumé of Research Work at Letchworth Village, by Dr. Howard W. Potter, clinical director at Letchworth Village, and most of these may be obtained in reprint form. Outcome of Mental Diseases in the United States, by Horatio M. Pollock.

* * *

The British press reports that Bond Street in London has recently opened a number of beauty parlors and rest rooms for pet dogs, where they may be bathed, curled and perfumed, while mistresses are shopping. Experts are provided to care for them properly and to feed them if they are left all day. Special diet kitchens have been added to prepare any sort of food specified by owners or favored by the petted darlings.

* * *

The very full and detailed report of the Jamaica Hookworm Commission has just been received in this country. It is a rich source of information on the subject for all interested.

* * *

Chewing gum is now exported from America to Europe, Asia, South America and Africa. American chewing gum is reported to be crowding out the ancient habit of betel nut chewing in the Near East. The industry of manufacturing gum is valued at more than Fifty Million Dollars, so that on the average of One million Dollars a week is spent for this strange luxury, and the makers are reporting their most prosperous year. Chewing gum originated in the course of experiments in 1860 to produce a substitute for rubber.—*N. Y. Times.*

* * *

Announcement has been made of the provision by the Mayo Clinic of Rochester, Minn., through an agreement with the Metropolitan Life Insurance Company, for an endowment fund for one hundred and thirty of its staff who have reached, or when they will have reached, the age of sixty-five. Each member of the group will be assured a fund based on his yearly salary, but not to exceed $10,000. In addition life insurance on a group basis equal to the amount of the endowment is provided. This insurance is a gift from the Clinic to the staff.

* * *

The *Manchester Guardian Weekly* for December 4, 1925, has an editorial under the caption "A Martyr to Healing Science" on the recent death of Reginald Blackall, one of the earliest experimenters with the curative possibilities of x rays. "His death was the end of a slow process which began when those rays had first been discovered more than twenty-five years ago, and when their effects on the handlers of them were hardly realized. One of Blackall's chief interests in recent years was to discover and perfect a method of complete protection for operators of x ray equipment.

* * *

The Massachusetts Society for Mental Hygiene has recently published a leaflet called *Twenty Aids to Mental Health for Adults.* It was prepared by Dr. Henry B. Elkind, director of the society. Two other pamphlets on different aspects of the mental hygiene problem have recently been issued by the New York State Committee on Mental Hygiene of the State Charities Aid Association. They were prepared by Dr. Stanley P. Davies, executive secretary of the committee, and are entitled *The Institution in Relation to the School System,* and *Improvement of Facilities for Care of Mental Patients Pending Commitment in New York State.*

* * *

Literary investigators state that they have discovered documents in the city of El Toboso, Spain, that once belonged to Dona Ana Martinez Zarco with whom the author, Cervantes, is believed to have been in love, and so made her the heroine, Dulcinea del Toboso, of his romance, *Don Quixote.*

* * *

Berlin traffic policemen, according to press reports, have recently been suffering so severely from the carbon monoxide fumes of automobile exhausts, that gas masks have been suggested. A recent epidemic of illness among the traffic squads is believed to have been a form of poisoning from benzol fumes. It manifested itself by severe headaches, general lack of vitality, and in some cases a state resembling coma.

* * *

The British press has been generous in its tributes to Dame Louisa Aldrich-Blake, dean of the London School of Medicine for Women, who died on December 28, 1925. She was considered one of the most able surgeons in England, and had done invaluable work during the war, and later as an administrator. A few months ago she was made a Dame of the Order of the British Empire by the King.

* * *

A study of four hundred children discharged from the ungraded classes of New York city schools is reported in the November number of *Ungraded.* The author is Margaretta Taylor, a visiting teacher in the Department of Ungraded Classes.

* * *

For *Harper's Magazine* for January the prolific Dr. Collins writes again, this time on Childish Americans. He analyzes the causes and evidences of our adult infantilism in his characterstic manner, and gives a list of symptoms for diagnosis.

* * *

Recent publications of interest to the medical profession are *The Conquest of Disease,* by David Masters (Dodd, Mead); *The New Age of Faith,* by John Langdon-Davies (Viking Press); *Pygmalion, or the Doctor of the Future,* by R. M. Wilson, one of the *Today and Tomorrow Series* (Dutton); *The Young Delinquent,* by Cyril Burt (Appleton); *Comes the Blind Fury,* a novel by Raymond Eschollier, translated from the French, with the title there of *La Nuit;* it is a story based on hereditary influences in the life of a young girl (Dodd, Mead); *What Evolution Is,* by George Howard Parker (Harvard University Press); *Collected Papers,* by Sigmund Freud (Hogarth Press, London); *Light and Health,* by M. Lukiesh and A. J. Pacini (Williams & Wilkins); *State Laws Relating to Special Classes and Schools for Mentally Handicapped Children in the Public Schools,* by Dr. Thomas H. Haines, reprinted from *Mental Hygiene;* and *Everychild: How He Keeps His Mental Health,* by Dr. Frankwood E. Williams, reprinted from *Annals of the American Academy of Political and Social Science.*

Some interesting facts are brought to light in a report recently made public by Dr. Arthur W. Gilbert, Massachusetts Commissioner of Agriculture, who has been making a study of the extent of damage to crops from thunderstorms. One of these facts is that fear of lightning is far out of proportion to the grounds for it. The chance of death from this cause is only one in more than a million. In a five year period nineteen persons were killed by lightning in Massachusetts, an average of 3.8 persons per year. The survey indicates that the farmer is ten and a half times as likely to be struck by lightning as the city man, because of the lack in rural communities of steelframed buildings, trolley wires, and other conductors that tend to relieve electrical tension before and during storms. On the other hand, the farmer is twenty thousand times safer from harm on his country roads than the city man dodging motor traffic in large cities!

Abstracts from Current Literature

RESPIRATORY DISORDERS

Tonsils.—Edmund Nobel and Adolf F. Hecht (*Klinische Wochenschrift,* May 28, 1925) state that the results from operations on the tonsils can be properly judged only by simultaneous careful consideration of the pathological physiology of the tonsils. Hypertrophy of the tonsils shows a maximum occurrence in the fourth and tenth years of life. Spontaneous retrogression of the tonsils may be expected with great likelihood after puberty. There certainly does often exist a relationship between diseases of the tonsils and other diseases, such as rheumatism, endocarditis, nephritis, etc., but can be definitely established or made probable only by observation of the clinical course. Tonsillectomy, done after the fifth year of life, undoubtedly reduces the tendency to anginas in ninety per cent. of the cases. Poor results were observed by the author in only seven cases among sixty-eight operations. Before the fifth year of life, however, a good result was found only in sixty-one per cent. of the cases (thirteen poor results among thirty-three cases).

Lobar Pneumonia: Deviations from the Typical Types with Particular Reference to the Temperature Curve.—I. H. Goldberger (*Archives of Pediatrics,* June, 1925) finds that uncomplicated primary lobar pneumonia in infants and children may be accompanied by a decidedly atypical temperature curve. There is a seasonal incidence in pneumonia, the predominance being in the spring. Infants under one year, and children over three years of age in the author's institution, were relatively immune to primary lobar pneumonia. Children in poor physical condition, although less susceptible to primary lobar pneumonia than those in good physical condition, predominated in the author's group of cases (fifty-nine per cent. characterized as poor compared to twenty-seven per cent. considered in good physical condition). Ninety-five per cent. of the twenty-two cases showed the characteristic triangular consolidation röntgenographically, of which seventy-three per cent showed the site of consolidation equally divided in the right upper and right lower lobes. Practically all lobar pneumonias begin at the periphery of the lung. This observation contradicts the term "central pneumonia" as it is commonly used. Lobar pneumonia may run its course in forty-eight hours, but the average is nine days. Temperature oscillations averaging six degrees may occur daily in lobar pneumonia (forty-six per cent of this series) and in some cases the intermissions may be as much as ten degrees. The roentgenogram is a positive means of distinguishing between bronchopneumonia and lobar pneumonia, whereas clinically, the differential diagnosis is often difficult and uncertain.

Massive Pulmonary Collapse.—A. Bertram Soltau (*British Medical Journal,* March 21, 1925) states that massive pulmonary collapse is a definite clinical condition which occurs far more frequently than is supposed. It is caused by inhibition of the diaphragmatic action, whether from reflex or inflammatory causes. Its onset is favored by the supine position. It follows direct trauma of the chest wall or lung, and surgical operations on the abdomen, even remote from the diaphragm.

It gives definite physical signs, which may simulate pneumonia or plural effusion. At first breath sounds are practically absent, or only the faintest respiratory "whisper" will be heard in the typical case. There is an associated absence of vocal resonance. The lung appears "dead" with no bronchial air passing through it. The sign-complex is therefore a retracted immobile chest with raised diaphragm, dull on percussion, and exhibiting neither breath sounds nor vocal resonance, and with the heart displaced toward the dullness. In the second stage there is a dramatic alteration. The percussion note is still dull, but the breath sounds are tubular or amphoric, and vocal resonance is greatly increased. Ventilation is commencing and the bronchial respiration becomes audible. In the final stage dullness becomes less pronounced, the tubular breath sounds are less definite, and frequently moist adventitious sounds are heard. With the expansion of the lung the heart returns gradually to its normal position. Pyrexia is not uncommon, but does not reach a high degree. The differential diagnosis depends on determining the position of the apex beat and the diaphragm. In cases of injury, the lung on the side remote from the trauma may be affected.

Very little can be done in the way of active treatment. Oxygen is essential for severe dyspnea, and should be given practically continuously. The semiupright position should be assumed by the patient.

Is Our Knowledge of Pneumonia Sufficient to Explain Its Endemicity and Occasional Epidemicity? A. C. Abbott (*American Journal of the Medical Sciences,* June, 1925) maintains that the evidence does not justify the belief that the endemicity and occasional epidemicity of the disease pneumonia are due to the simple transference of one or another of the types of pneumococcus from the sick to the well. The fact that recovery from pneumonia confers no appreciable immunity from subsequent invasions by the homologous type of pneumococcus (or by other types) justifies a question as to the etiological relationship of that organism to the disease pneumonia.

The occurrence of pneumonia as a result of the activities of diverse organisms suggests the possibility that the lesions of the lungs are but secondary to an antecedent general or local condition brought about by some other as yet unidentified organism. If the pulmonary lesions may be regarded as secondary developments, may not the spread of the disease be explained by the existence of some, as yet unknown, predisposing agent; and may not invasion and transmission occur before the disease is recognizable as pneumonia? This would explain the persistent, ubiquitous, high rate of morbidity as well as the occasional epidemic explosions.

Significance of Anaphylaxis in Pneumococcus Immunity.—George M. Mackenzie (*Journal of Experimental Medicine,* January, 1925) subjected guineapigs to immunizing injections of pneumococcus, titering the immunity at frequent intervals, and testing for the appearance and duration of allergy and anaphylaxis. Despite the presence of a high degree of active immunity and strong protective power in the serum, it was not possible at any time during the course of the experiments with immunized animals to demonstrate the presence in the serum of either precipitins or agglutinins. At no time was it possible to demonstrate any cutaneous allergy to protein extract, filtrates, or whole killed cultures. During the course of an artificially produced active immunity, anaphylaxis may at times be present and at times absent without any measurable effect upon the resistance of the animal to infection by intraperitoneal injection. In the particular instance studied, the experiments indicate that anaphylaxis to pneumococcus protein has no important effect upon the resistance of the animal to infection. It appears to be a concomitant without any significant rôle in the immunity mechanism.

Causation of Postoperative Pneumonia.—H. Featherstone (*British Journal of Surgery,* January, 1925) finds that in postoperative pneumonia the anesthetic agent and the method of administration, save in special cases, seldom are decisive factors; general health and local disease of the lungs on the other hand may play a considerable part. He describes the process of collapse as follows:

Owing to the pain at the point of incision (usually abdominal) the patient does not breathe fully and the lower lobes of the lungs do not freely expand and contract, so that congestion of blood with edema sets in. The bronchioles of the disordered region are more or less choked by this swelling of their walls, which has, perhaps, been increased from irritation by the anesthetic agent. Into this motionless and wellnourished region, germs and particles of débris arrive. The mode of access may be by the air or by the blood or by the lymph. In these circumstances the patient cannot cough owing to pain, and the exudate and the débris, which should have been expectorated or evacuated by the ciliated epithelium, lie undisturbed in the lower lobes. Closure of the bronchioles in this nearly motionless area, and absorption of air from the alveoli, now ensue. The result of the process is massive collapse of the lung or, according to Whipple, pneumonitis.

When the infection is particularly virulent, if the patient's resistance is low, and if the diaphragmatic paralysis persists, we shall not be surprised to find true bronchopneu-

monia as the sequel, and it will be of coalescing lobular distribution, chiefly in the lower lobes, affecting those lobules whose obstruction determined the collapse of that portion of the lung. At operation, every care should be taken to prevent loss of heat, of fluid, and of blood, and especially exhaustion from trauma to nerve tissue, and to highly vascular parts. Infection of the lung is often by means of aspiration in the presence of certain other factors. Severe sepsis in other regions affects the lung via the bloodstream. There is evidence that lymphatic infection through the right half of the diaphragm leads first to pleurisy and then to pneumonia. In the absence of severe sepsis, operations on the abdomen, and especially the upper abdomen, provide the start of the chain of events which leads to pneumonia. Pain in the abdomen from operative trauma, or from inflammation, gives rise to rigidity of the anterior abdominal wall and to reflex inhibition of the diaphragm, together with some spasm of the lower intercostal muscles.

Experimental Pneumonia in Mice Following the Inhalation of Streptococcus Hemolyticus and of Friedländer's Bacillus.—Ernest G. Stillman and Arnold Branch (*Journal of Experimental Medicine*, May, 1925) found that the persistence of streptococcus hemolyticus in the lungs of mice following inhalation was irregular. The organism may be recovered as late as the seventeenth day after exposure. Tests for contact infection showed that this played no part in the mortality from streptococcus septicemia. Normal mice sprayed with Friedländer's bacillus also showed the organisms in the lungs and heart's blood a number of days after exposure. A large number of these animals die of a septicemia during the thirty days following spraying. In normal mice exposed to pneumococci, the organisms rapidly disappear from the lungs, and only an occasional animal develops pneumococcus septicemia. However, if the mice are first alcoholized, the pneumococci persist for a longer time in their lungs, and a number will die of septicemia.

Massive Collapse of the Lungs.—C. Jackson and W. E. Lee (*Annals of Surgery*, September, 1925) discuss the mechanism of this disease and its relation to foreign bodies in the bronchi and to postoperative complications, concluding that acute massive collapse or massive atelectasis is a phenomenon which has been recognized in association with varied conditions. Although diverse they have two factors in common which we believe have some bearing upon the etiology of pulmonary collapse, namely, embarrassment or paralysis of the respiratory movement and obstruction of the bronchial tubes. The interference with the respiratory movements may be as slight as that resulting from posture and may increase to that of the voluntary or reflex inhibition from postoperative pain of abdominal operations, or even reach the complete paralysis which occurs in diphtheria. Obstruction has been found to be caused by foreign bodies, bronchial secretion or extrabronchial pressure as is produced by tumors.

Massive collapse of the lungs is a comparatively rare condition and its incidence postoperatively is approximately greater than eight per cent. However, it has a definite surgical significance which should not be overlooked. The most characteristic sign is displacement of the heart towards the collapsed lung. Partial collapse of the lung is probably a frequent complication following abdominal and particularly upper abdominal, operative procedures. The arrest, in these areas of partial collapse, of multiple emboli coming from the operative field is probably the mechanism and the lesion which so frequently occurs after operative procedures, and which is commonly called postoperative or postanesthetic pneumonia.

When infection is added to these minute multiple infarctions in the collapsed areas a true bronchial pneumonia is established. This we believe is rare compared to the frequency of partial collapse combined with minute pulmonary emboli and infarction.

If two of the factors underlying pulmonary collapse, either massive or partial, are 1, inhibition or arrest of respiratory movements and 2, subsequent obstruction of the bronchi with accumulated bronchial secretion, there are definite indications for prophylaxis and treatment of this condition. The minimizing of the trauma of all operative procedures, the conservative use of morphia and other inhibitors of the normal bechic or cough reflex; and the avoidance of fixed or unnatural positions postoperatively would seem rational procedures. The choice of such anesthetic agents as have the least irritating effect upon the bronchi and result in the minimum bronchial secretions, as local anesthesia, gas oxygen anesthesia and ethylene, are mandatory. All these measures are prophylactic. After the condition of massive collapse is established the dangers are not in the lesion itself, unless it be bilateral, but in the complications which are apt to ensue, as pneumonia in one of our cases, empyema and lung abscess. The fact that of the recorded cases that have recovered spontaneously the average duration of the recovery has been about twenty-one days and that in the case here reported seventy-two hours after removal of the obstructing bronchial secretion the lung had been restored to its normal condition, is at least suggestive.

Cytology of the Sputum.—Emanuel Propper (*Schweizerische medizinische Wochenschrift*, July 9, 1925) finds that for a thorough study of the cells in the sputum the moist fixation of Liebmann and the staining with hemalum-eosin are the most useful. The Pappenheim staining method is the best for the granules. The moist fixation method is also suitable for a study of phagocytosis.

In order to know in what part of the respiratory tract a sputus originates, we must stick to the principle of the characteristic epithelium of the various portions of the tract. Every pulmonary sputum contains alveolar epithelium. It does not play the important part in the socalled desquamative pneumonia heretofore believed; they also occur as cardiac decompensation cells and as macrophages of coal pigment.

The sputum content of polynuclear cells and neutrophiles is considerable and aside from their part in immunity, their main work lies in the phagocytosis of bacteria, especially tubercle bacilli. This phagocytosis of tubercle bacilli in the sputum is almost universal. There appears to be a diminution or even disappearance of the granules in pulmonary tuberculosis.

Eosinophiles are frequently found in the sputum, and they are markedly increased after injections of tuberculins. This may be used as a favorable prognostic sign. A precritical sputum eosinophilia is an equally favorable prognostic sign in croupous pneumonia. Here the eosinophiles usually have two nuclei and originate in the blood. Lymphocytes are found in only a small number in the sputum. The monocytes in the sputum are probably of reticuloendothelial origin. Their frequent occurrence is observed in caseous pneumonia and in chronic pulmonary tuberculosis with an unfavorable prognosis, where they are to be considered as a specific tissue reaction.

Pfeiffer's Influenza Bacillus Meningitis.—Walter Schnyder and Eugen Urech (*Schweizerische medizinische Wochenschrift*, June 11, 1925) draw the following conclusions from the clinical course and their bacteriological and pathologicoanatomical findings in seven cases described and fifty-six other cases collected from the literature:

1. The Pfeiffer bacillus is not a rare excitant of acute meningitides.
2. The age of early childhood (up to three years) is affected most frequently.
3. The nasopharyngeal space, the air passages, and the auditory apparatus serve as the chief portals of entry.
4. The diagnosis can be established definitely only by bacteriological examination.
5. The prognosis is unfavorable. In the sixty-one cases only six patients lived. The cure is followed by serious sequelæ, such as deafness, and in one case blindness was observed.
6. The duration of the disease is short and rarely is more than one to fifteen days.
7. Pathologic anatomically there is an acute suppurative leptomeningitis affecting chiefly the base and frontal portion of the brain, and less often the convexity.
8. Epidemiologically, the meningitis produced by the Pfeiffer baccillus resembles the meningococcus meningitis most closely. It usually appears sporadically.

The authors' cases and those selected from the literature did not occur during the prevalence of a wide grippe epidemic. The authors believe that the Pfeiffer bacillus may be considered as a definite excitant of acute meningitis. Like the meningococcus, it is a pus inciter and occasionally may even produce a septicemia. The authors' observations are not sufficient to enable them to give the Pfeiffer bacillus an etiological significance in pandemic grippe.

Extrapleural Thoracoplasty.—H. M. Davies (*British Journal of Surgery*, July, 1925) records his technic, a modification of the Wilms type of operation, in detail. His attitude in a few of the controversial points associated with this procedure are as follows:

Chloroform for the very light anesthesia required, supplemental to the local, in order to keep the patient asleep during the operation, is the anesthesia of choice. The question of postoperative pain is of great importance, as on the absence of this depends so much the ability and the willingness of the patient to cough and to bring up the accumulated expectoration. It is for this reason that the author injects into the neighborhood of each nerve five mm. of absolute alcohol, so as to obtain an anesthesia which will continue until the healing processes—including the rounding off of the cut ends of the ribs—have become complete. The operation should be done in one stage if possible, but always having the greatest regard to the safety of the patient. If the patient's general condition is good, if there is no difficulty in respiration when on the table, and the color is satisfactory, if the sputum is not excessive and likely to flood the bronchial tubes when the lung collapses, and the disease is not acutely active with considerable complicating secondary infection, then the operation is started off with the complete incision as for a one stage operation. If there is any doubt, however, as to the patient's ability to tolerate the complete rib resection, the operation is begun as though for a two stage undertaking. When this first part is completed up to and including the rib excision, the condition of the patient is considered, and if this appears to justify it, the second stage is carried out. It is most important for efficient collapse that, after the operation, the scapula should sink right in so that it lies at a deeper level (i.e., more anterior) than the posterior surface of the transverse processes. Owing to the changes in position of the freed end of the ribs, already mentioned, this falling in will take place even if the whole of the ribs underlying the scapula are not excised.

Nasal Disease.—M. J. Gottlieb (*American Journal of Surgery*, July 1925) states that retrobulbar optic neuritis is caused in the great majority of cases by disease of postethmoidal and sphenoidal sinus. If time permits all other causes should be excluded before operating. If time is precious one is justified in opening up the sinuses without further investigation. The element of haste is so important that it cannot be overemphasized. The middle turbinates should not be spared in any instance.

Production of Immunity with a Soluble Antigen of the Pneumococcus.—N. S. Ferry and L. W. Fisher (*Journal of Laboratory and Clinical Medicine*, July, 1925) obtained an aqueous extract of Type I pneumococcus from the washings of this organism which was fairly stable at a temperature of 60° C. for one hour with antigenic properties extremely high, without resorting to chemical extraction, and suggests the possibility of the use of such an extract for prophylactic purposes against pneumonia in the human.

TUBERCULOSIS

Tuberculosis of the Tongue.—J. M. T. Finney and J. M. T. Finney, Jr. (*Surgery, Gynecology and Obstetrics*, June, 1925) state that direct trauma seems to be the only important causative factor. In no case was the trauma to be charged to that popular bugbear, the pipestem. The majority of the patients were in the forties; it might, therefore, be classed as another of the "afflictions of middle life." There is no site of predilection for the development of lesion; any portion of the tongue may be attacked, with most of the lesions occurring anterior to the circumvallate papillæ, and about equally divided between tip, margins and dorsum. The tongue lesions may be single or multiple. There may or may not be any regional adenopathy; in none of these cases was glandular enlargement very marked, and in several it was entirely absent. It would seem wise, in a case which seems to be primary, to treat it by wide excision, much as if it were carcinoma.

Tuberculoma of the Cecum.—F. C. Herrick (*Annals of Surgery*, April, 1925) finds that there occasionally occurs in tuberculous patients a tuberculous process localized chiefly in the cecum or colon and characterized by a predominance of scar tissue and roundcell infiltration to a degree closely simulating new growth. This process has been called hyperplastic tuberculosis, but recently authors agree on the term of tuberculoma as more descriptive. It is apparently noted more commonly in the pathological than the surgical departments. By causing chronic incomplete ileus this condition may produce a major handicap in the recovery from pulmonary tuberculosis. The chief errors, both in preoperative and operative diagnosis are, calling it appendicitis in young adults or cancer in middle or later life. Incomplete or complete ileus may furnish the first definite symptoms. In several classical cases and some reported more recently, histological differentiation was difficult or impossible. Treatment in young adults consisting of a simple exploratory operation or an exclusion anastomosis has been followed by excellent results. Resection is preferable in good surgical risks. In an old patient where differentiation from cancer can be made an exclusion anastomosis is preferable.

Thoracoplasty for Pulmonary Tuberculosis.—J. Alexander (*Annals of Surgery*, April, 1925) asserts that the high incidence of tuberculous pneumonia following resection of the lower ribs is due principally to impairment of the function of expectoration. Substitution of radical phrenicotomy for resection of the lower ribs, as the first operation to be performed, will probably lessen the danger of postoperative pneumonia as well as reduce the frequency with which fresh small tuberculous lesions develop in the unoperated lung. In cases in which there is little or no clinical tuberculosis in the lower lung and in which the diaphragm rises well into the chest after phrenicotomy, resection of only the upper seven ribs has, in the author's opinion, important advantages over the one stage or two stage thoracoplasty of ribs XI to I, which is now in general use. The combination of primary radical phrenicotomy and secondary resection of the upper seven ribs is worthy of extensive trial in such cases. When the lower lung contains more than a few tuberculous lesions, or when the diaphragm rises only a little into the chest after phrenicotomy, the lower ribs should be resected as the third stage of the operation.

Rôle of Monocyte in Tuberculosis.—R. S. Cunningham, F. R. Sabin, S. Sugiyama, and J. A. Kindwall (*Bulletin of the Johns Hopkins Hospital*, October, 1925) present as a new factor in the study of tuberculosis the concept that it is a disease which affects primarily a single strain of cells, namely, the monocytes. Evidence is presented to show that the infection of tuberculosis causes an overproduction of the monocyte, including all of its stages, namely the reticular cells, the typical monocyte and its two derivatives, the epithelioid cell and the giant cell; that the tubercle bacillus so alters the cytoplasmic activity of the monocyte that the cell becomes a suitable medium in which the bacillus can live and multiply, or in other words, that the organism of tuberculosis becomes a parasite within the cell; and that the marked overproduction of monocytes in the connective tissues is correlated, in the acute phase of the disease, with an increase in monocytes in the circulating blood. This new concept of the essential nature of the disease and the observation that it is possible to correlate the progress of the disease with changes in the circulating blood opens up a new experimental attack on tuberculosis, and the authors think it probable that the fact that the organism of tuberculosis can live as a parasite within the monocyte may mean that the bacillus is thereby protected to some degree from the usual reactions of the body against it.

Complement Fixation in Tuberculosis with Particular Reference to a Group of 102 Positive Reactions.—Lloyd R. Jones (*Journal of Laboratory and Clinical Medicine*, July, 1925) did a tuberculosis complement fixation test on 617 patients with one particular lot of antigen. There were positive results in 102 of the remaining 400 giving a negative test, it was recognized that many were tuberculous, but the purpose of the work was merely to determine the presence of tuberculosis among those giving a positive reaction. Of the 102 positive cases, fifty-five were active cases of pulmonary tuberculosis, with tubercule bacilli in the sputum; twenty-two were active clinically, but with negative sputum; twenty-one were pulmonary tuberculosis quiescent clinically, but with well defined evidence of former tuberculous process; one case was negative clinically, but was a case of syphilis with a positive Wassermann, and three other cases were also negative clinically, but respectively had laryngitis, asthma, and in the third instance, no positive clinical condition. Concerning the socalled cross

fixation or nonspecific fixation with leutic sera, ten cases gave a positive Wassermann and a positive tuberculous complement fixation test concomitantly, but in all but one the diagnoses of syphilis and tuberculosis were made, the one exception being considered clinically tuberculosis free. In employing this test an antigen preparation should be accepted only after thorough preliminary trial, showing satisfactory antigenic qualities. The amount to be used in the test can be determined only after careful experimentation, and must be such as permits a very fine quantitative adjustment between complement, antigen, and patient's serum. Several control sera should be regularly employed to detect evidence of false fixation, antigen deterioration, etc. The limited observations reported tend to suggest that positive reactions as obtained with the test when correctly performed, indicate with a high degree of accuracy the presence of tuberculosis "reaction bodies" irrespective of whether the disease is then clinically active or quiescent.

Early Diagnosis of Pulmonary Tuberculosis.—Ian Struthers Stewart (*Glasgow Medical Journal,* September, 1925) says that a typical early case would present the following symptoms and physical signs: There would be present cough, lassitude, and pyrexia, and, on examination, deficient expansion, faint or harsh inspiration, with possibly, after coughing, a few fine crepitations in the axilla, round the nipple, or under the clavicle. Radioscopic examination would show deficient movement of the diaphragm on one side with a shadow or shadows extending into the lung substance. Evidence of dense consolidation would be obtainable neither by clinical nor by radioscopic examination.

Tuberculous Disease of Joints.—C. H. Fagge (*Clinical Journal,* August 19, 1925) says that much can be done for hip disease if it is seen in the first stage. If not seen until there is adduction and shortening, possibly in the presence of an abscess, obviously the results will not be as good as if the child had been seen when it began to limp. The second factor is the social class of the patient. The poor child will not be seen at as early a stage as the child with a more careful mother. As in many diseases in children, the prognosis is exactly proportionate to the social class affected. In the early stage of tuberculous disease the formation of an acute abscess, often with the presence in the pus of staphylococci, or even streptococci, shows that destruction is great and the resistance small. In the later stages the formation of a cold abscess does not seem to be of so bad a prognostic significance. In fact, the author believes that the formation of a cold abscess is the last struggle of the tubercle bacilli, and when this abscess has been aspirated the disease subsides and the joint consolidates.

Before aspirating such abscesses there should be definite indications, such as the swelling getting larger, or tending to point. The mere presence of pus in relation to a joint in the form of a cold abscess is not, by itself, a positive indication to evacuate it, because this cannot be done without risks. Small collections of pus arising from tuberculous joints often disappear under continued rest. The author has not found that the injection of these abscesses with any material such as camphor, thymol and sulphuric ether, i. e., two parts camphor, two parts thymol and one part sulphuric ether, was of any value, nor the injection of iodoform. The great thing about evacuation of these abscesses is to introduce a fairly large needle some distance from the surface of the abscess, so as to go through healthy tissue before entering the abcess, and then to do all you can to prevent subsequent staphylococcic invasion. Unfortunately, careful as you are, staphylococcic infection will occasionally occur. In my experience, staphylococcic infection of a tuberculous joint is generally the most potent factor in inducing a fatal ending.

Spleen Extract in Tuberculosis.—Bayle (*Presse médicale,* September 23, 1925) maintains, after twenty-two years' experience, that spleen extract, given hypodermically or by mouth, is of pronounced value in tuberculosis, whether of the lungs, bones or joints. Splenic opotherapy has been shown to increase the number of red and white cells and the hemoglobin percentage, to increase the ratio of lymphocytes and cause eosinophiles to appear, to reduce the elimination of phosphates and increase the blood calcium, to enhance connective tissue deposition about tuberculous foci and promote healing, and to cause reduction of the number of tubercle bacilli, granular changes in these organisms, and finally their disappearance. Several experimenters, including the author, have found spleen injections strikingly effective in the prevention and treatment of tuberculosis in guineapigs and rabbits. In man, there is prompt and lasting improvement in the general condition, weight, cough and dyspnea, blood, tuberculous lesions, phosphaturia, and tubercle bacilli. For oral use, the hog spleen is put up in a syrup, each tablespoonful of which represents twenty-five grams of the organ. This mode of administration is employed in patients having merely anemia or slight glandular swellings; prophylactically in the associates of consumptives or in convalescence from severe illnesses, and in general, as an auxiliary to the hypodermic treatment when the condition of the stomach permits. The dose in adults is four tablespoonfuls daily with the meals; in children below three years, one teaspoonful daily for four days a week, and at the intervening ages, proportionate amounts. In adults and children above ten years, the syrup is given in courses of twenty-one consecutive days, with intervening periods of one to two weeks. Whenever there are definite tuberculous lesions, hypodermic spleen medication is indicated. An extract of hog spleen in five mill ampoules is used. In adults the single dose is one to two ampoules. One entire ampoule is used even in children of four years. The injections may be either subcutaneous or intramuscular, preferably in the abdominal cellular tissue or the buttocks. The injections may be regarded as painless, and never induce fever or anaphylactic phenomena. Twelve injections are given in pairs on successive days, with intervals likewise of two days, the entire course of twelve injections thus occupying twenty-two days. The treatment should be continued for a few months after cecovery. At the same time the usual treatment by diet, fresh air and rest is applied in pulmonary cases, with ovarian, thyroid, parathyroid or adrenal gland when indicated. In osteoarticular forms, immobilization in plaster or silicate apparatus is needed only for a relatively short time, on account of the treatment by spleen extract.

Pneumoperitoneum in the Treatment of Tuberculous Peritonitis.—W. Nelson Mercer (*Virginia Medical Monthly,* June, 1925) asserts that the simplest, safest and most logical method of treating tuberculous peritonitis with ascites is to remove the fluid with a cannula and to follow this by an injection of filtered air into the peritoneal cavity by means of a pneumothorax apparatus. This may be repeated as often as necessary until all fluid has disappeared without producing any harmful effects upon the patient.

Bronchial Gland Tuberculosis.—John B. Hawes, 2d, and Eli Friedman (*Boston Medical and Surgical Journal,* May 14, 1925) state that at the present time there is an amazing difference of opinion among x ray men and between röntgenologists and clinicians as to the interpretation of x ray shadows of the hilus region in children. There is no apparent unaminity of opinion as to what constitutes normal or abnormal, tuberculous or nontuberculous, active or inactive, old or recent. The whole subject of the diagnosis of bronchial gland or hilus tuberculosis is still in a stage of doubt and uncertainty. "Signs" at the best are unreliable and x ray evidence at present of little value. Diagnosis should be based on history, exposure, positive von Pirquet, and constitutional signs and symptoms.

FRACTURES AND DISLOCATIONS

Open Reduction of Fractures.—A. L. Soresi (*Journal of Bone and Joint Surgery,* April, 1925) declares that open reduction of fractures by the no foreign bodies and tight fitting window cast technic, represents an advanced step in the treatment of fractures. In the cases in which the method was applied by the author results have been most satisfactory, none of the complications common to the other methods of open reduction, such as infection, osteomyelitis, necessity of removing the foreign bodies used for osteosyntheses, delayed union, painful limbs, or deaths, were observed. In cases where infection was present no unpleasant complication was noted; the results were as satisfactory as in the clean cases. This fact demonstrates that complications noted when other methods are followed are due to the presence of the foreign bodies used in the process of osteosyntheses. It follows that foreign bodies prevent the proper formation of callus and favor infection, while direct good coaptation of the fractured ends of the bone, presence of blood, complete absence of foreign bodies in the wound, mean better union, because callus formation is not hindered; better function, by preventing infection, damage to nerves,

blood vessels, muscles and tendons. Contrary to the generally accepted opinion, bones can stand a great deal of trauma and infection, the ordinary usual complications following trauma and infection being due to the presence of foreign bodies, which are injurious to the process of bone repair.

Fractured bone should be reduced and maintained in proper position without leaving any foreign body in the wound. A cast that is applied without padding the limb is indispensable to maintain the proper coaptation of the fractured bones. The elimination of foreign bodies and the application of the tight fitting cast allow the greatest comfort to the patient.

Fractures of Carpal Navicular Bone.—K. Speed (*Journal of Bone and Joint Surgery*, July, 1925) advises that the treatment of recent navicular fracture—that is, a day or so old—is immediate immobilization of the hand, thumb, and wrist in a position of slight radial and volar flexion. This immobilization should last seven or eight weeks and should be followed by graduated active use, with daily baking by dry heat. If a happy outcome is desired, no pain should ever be set up by overuse or early hyperrange of motion of the wrist.

For old fractures—and we call them old if they have gone undiagnosed seven days or longer—the best and most satisfactory treatment is carpalectomy of the navicular. No matter how many fragments are present, all the bone is removed. I find no reason for leaving the distal fragment: it always sets up irritation and eventually causes symptoms equal to old fracture. Two patients have come to me from whom the proximal portion of the fractured navicular was removed. After several years subsequent falls caused a volar dislocation of the lunate—perilunar transnavicular dorsal dislocation of the wrist.

The earlier the bone is removed, the better the result. In cases of no greater duration than six months the prognosis is very good. If the fracture has existed five to ten years, the prognosis is not so good, but by taking out the entire bone pain can be completely, and stiffness partly, removed. If the carpus is truly in a condition of bony ankylosis, a wrenching of the hand into a cock-up position may improve the function, but a carpalectomy of the whole proximal row leads to better results. For these long standing fractures with bony ankylosis after carpalectomy of the proximal row, a fascial transplant is inserted in the radiocarpal joint as in arthroplasty. Active and passive use are started as soon as the operative wound has healed.

Fractures of the Lower End of the Radius.—R. M. Carter (*Surgery, Gynecology and Obstetrics*, September, 1925) states that a thorough knowledge of the anatomy of the parts and the mechanism of the usual fracture is essential to proper treatment. It is probable that no one mechanism will satisfactorily account for all cases. The mechanisms fall into three general classes, depending upon direction and mode of transmission of the active forces, as follows:

The force is transmitted by means of bony segments exclusively, no ligaments being involved. To this class belong the theories of Dupuytren, Nélaton, and Malgaigne.

The force is concentrated upon the anterior radiocarpal ligament, which tears off a fragment. Here belong the theories of Le Comte, Tillaux, Delbet, Contremoulin, and Pilcher.

The force follows a complex course from humerus to ulna, and from ulna to radius, by way of the interosseous membrane. This view is defended by Lopes and Hennequin.

Any of these, or combinations of them, may be active in any given case. Successful treatment of these fractures consists in immediate, complete reduction, preferably under an anesthetic, and early passive motion and massage. Operative treatment, as a rule, is indicated only in old, badly treated or undertreated cases.

Fracture Calamities and Their Management.—J. O'Conor (*Annals of Surgery*, January, 1925) finds the following method of procedure rapid and effective in cutting bone grafts.

When the site for the graft has been prepared, take the dimensions of the graft required by cutting a piece of thin lead foil to its exact size and shape. Then expose the periosteum through a corresponding area over, e.g., the anterior surface of a tibia. Guided by the application of the mould to the part, with scalpel, make two transverse incisions through the periosteum, one at the upper and the other at the lower border of the mould, sufficient for the application of an osteotome whose width at least should be double that of the graft required. The bone is then divided above and below transversely into the medullary canal.

The mould still retained its position, i.e., over the bone central between the limits of the two transverse osteal sections, the periosteum is then incised along the lateral margins of the mould joining the transverse lines. Commencing at one end of a longitudinal line with osteotome the bone is lightly grooved, in due osteal grain, from one transverse section to the other by gentle taps with a hammer. A narrow furrow is next similarly outlined on the other side.

The reason for employing an osteotome much broader than the graft required will now be obvious in that the two longitudinal grooves begin and end distinctly within the compass of the transverse sections. Attention to this detail insures a direct line in proper plane and excludes any possibility of splitting the bone above or below the limits defined for removal of graft when the osteotome is made to complete the bilateral osteal division into the medulla. The graft, with its periosteum intact, is then levered out and directly applied where required. This wound is at once closed by through and through silkworm gut sutures, each of which is made in transit to embrace any periosteum available. The tibial wound is then sutured.

Dislocation of Shoulder.—W. W. Plummer and F. N. Potts (*Journal of Bone and Joint Surgery*, January, 1925) suggests a technic, applicable to recurrent anterior shoulder dislocation, for the purpose of applying a check to the anterointernal slipping of the head.

With the patient on his back, and the arm at the side in a position equivalent to the middle of the arc of rotation of the humerus, an incision is made just external to the greater tuberosity and in the long axis of the arm. The incision should extend well up on top of the acromion and below the surgical neck of the humerus. The fibres of the deltoid are separated, and the underlying capsule (or better, connective tissue investiture of the joint) bared and cleared to expose the anterior and external edge of the acromion. From the thigh a strip of fascia lata five or six inches long by one inch wide is dissected, divided into two narrow strips to be used for the transplants. A coarse, full curved needle is threaded to each end of each strip. The needle on one end of the first strip of fascia is carried through all of the layers down to bone at the base of the greater tuberosity, avoiding the biceps tendon, and in a direction upwards toward the anterior tip of the acromion. The needle point emerges here and is passed through a small drill hole in the edge of the acromion to bring the end of the fascial strip upon the upper surface. This has taken half of the first strip. The needle on the other end of the same strip is now inserted at the base of the greater trochanter a little external to the first suture and brought up through the acromion as before. The two ends of the fascial strip are drawn tight and sewn together and to the top of the acromion with No. 1 chromic gut. The second fascial strip is implanted in a similar manner external to the first. The wound is closed in the usual way and the arm dressed at the side in sling and thoracic binder. We have in effect now two fascial transplants to the shoulder capsule in the form of two double mattress sutures. These sutures, being short and placed as they are, tend to limit movements of the head; first, away from the acromion by their tension; second, rotation in both directions, for the same reason. It was assumed that abduction would also be limited due to traumatising of the subdeltoid bursa and thickening about the greater tuberosity. This limited abduction has followed in both the cases operated, but has not persisted in the degree of limitation that might have been expected.

Preserving and Restoring Function in Fractures.—R. T. Tunstall (*American Journal of Surgery*, August, 1925) suggests a method of transplanting living periosteum, developing bone cells, and maintaining firm fixation without interfering with circulation, as follows:

"Some time ago I was led to the conclusion that some form of periosteal graft would be the most useful and give little disturbance of the circulation, and that, with it, the vascular buds from the host bone might readily find avenues for union and rapid reestablishment of circulation. Accordingly I have adopted the plan of removing only a

minute layer of cortical bone in order to preserve the penetrating branches from the periosteum. It can hardly be called an osteoperiosteal graft, but this very thin layer of cortex enables one to handle the periosteum more easily, imparting some stiffness to it as well as protecting the small vessels. This periosteum is applied around the bone defect as a sleeve, or bridges it, in strips, as boards across a gap; rolled up lengthwise, it may be interposed between fragment ends, where there is much loss of substance.

"When I determine the amount of periosteum needed, usually from the tibia, I mark out with a scalpel the area to be removed and with the fine Albee crosscut saw penetrate the cortex about a millimetre. With an osteotome this is removed with the periosteum. The graft is put in a gauze handkerchief moistened with normal salt solution and, to avoid drying, is transferred as soon as possible to the site of the implant. The bone ends have previously been freshened, all fibrosed tissue has been removed and longitudinal scarifications of periosteum on fragments made to produce reactive stimulation and to open up vents for new circulation."

Epicondyle Fracture.—I. Zadek (*American Journal of Surgery,* September, 1925) states that fracture of the medial epicondyle should be treated with the elbow in full extension, for in this attitude the carrying angle can be properly restored. One cannot be certain of its restoration with the elbow treated in flexion. It is stated that the elbow should be immobilized in flexion to relax the attached muscles and prevent displacement of the fragment across the front of the elbow joint. Practically there is no tendency to displacement some days after injury.

Supracondylar osteotomy for correction of cubitus varus is likely to be unsuccessful if attempted correction is made with the elbow flexed—an attitude used by some operators, probably on the general rule that all fractures at the elbow, except those of the olecranon, should be treated in an attitude of flexion.

Amputations in Industrial Surgery.—W. L. Estes (*Annals of Surgery,* January, 1925) finds that amputations for industrial injuries owe their fatalities chiefly to loss of blood, or to other injuries received at the same time as the one requiring the amputation. The average death rate for single major amputation should, however, be low.

The surgeon should not amputate until the patient has reacted from shock. This will be indicated by the blood pressure. To avoid the danger of sepsis the operation should be done, if there is no strong contraindication within three hours after the injury was received. Care must be taken to control hemorrhage in delayed operation.

Synergic anesthesia seems to be best in operating for serious industrial injuries. Chloroform should never be used, and only little, if any, ether.

In common with all other industrial injuries there should be for "amputated" men a period of rehabilitation in the hospitals. The stump should be exercised, massaged and manipulated so that it shall be prepared for wearing and using properly a prosthetic apparatus. Artificial limbs should be applied just as soon as the stump is solid enough to bear them or bear upon them. For a leg or thigh amputation, the artificial limb should be worn within two months after the operation. It is true that the stump does shrink after a little while, but so do the unused muscles of the extremity. If the false limb is delayed for four to six months there will have occurred so much atrophy that the stump will be too weak properly to operate the rather heavy false limb.

Final compensation adjustment should be delayed for at least two years after an amputation, for the majority of work people will be able to earn quite as much as they did before the injury, by this time, if they have lost one leg or a part of one lower extremity below the mid thigh region No prosthetic appliance can fully or nearly fill the need of a lost upper extremity.

Amputations of forearms and upper arms produce as a rule irremediable disability, but the person who has lost an upper extremity may learn to do many things by the use of very homely and sometimes homemade prosthetic apparatus. No apparatus which imitates the appearance of a lost hand or forearm is ever of any great use in the everyday duties of a workman. Homemade hooks and clamps, which may be inserted or fastened to the end of a simple socket fitting over the stump of an arm, assist greatly and are useful helps in doing a workman's daily employment.

New Method of Reducing Dislocated Bones.—C. C. Booth (*International Journal of Medicine and Surgery,* February, 1925) describes a method for use when extreme flexion under ether fails of accomplishment. It was first employed upon a wrist thus:

Making a Crile dissection, the author exposed the anterior edge of the semilunar bone without the least difficulty. He then inserted the small end of an Allis dissector above the edge of the crest of the bone, and pushed against the bone and with very little effort tipped it backwards beneath the os magnum. Many short bones and short pieces of long bones can be reduced to normal location by this method with a very small skin incision. The key to this treatment is the stereoscopic x ray examination.

Fractures of the Femur.—J. E. Cannaday (*International Journal of Medicine and Surgery,* January, 1925) states that when pain results during the early period of traction, it is due either to defective technic of application or to improper care of the patient afterward.

The objection has been made that calipers may cause the development of a bone sinus. If the caliper is driven in too deeply, this may result, but if it penetrates only through the bone cortex and stops there, there can be no such thing as the development of a sinus.

The author's observations lead him to believe that the tertiary form of syphilis can be entirely ignored during the treatment of a fracture.

The most important consideration in regard to the treatment of a fracture of the femur is the early application of traction before there has been time for muscular contraction to take place. This he considered exceedingly important. He believes that occasionally even yet someone will advise that the fracture wait for a day or two until some of the soreness leaves. By that time the patient's muscles have contracted to such an extent that twenty-five to fifty per cent more weight will have to be applied in order to draw them out to their full length again.

Newer Methods for Nonunion of Fractures.—R. T. Taylor (*Surgery, Gynecology and Obstetrics,* June, 1925) asserts that many methods have been employed to hasten and even to produce union in congenital pseudoarthrodeses, delayed union or nonunion in bones, but the one that chiefly commends itself to consideration is one that furnishes tissue rich in osteophytes and other osteogenetic agencies or forces, such as the osteoperiosteal graft which obeys biological and physiological requirements plus rigid and prolonged mechanical fixation, as obtained by a boneclamp, that will assure alignment and at the same time not interfere in the least with the blood circulation in bone or periosteum.

It is conceivable that we may secure this by means of both a combined Albee inlay and Delagénière osteoperiosteal graft, as one or separate elements. The latter needs no explanation, but the former may be obtained by lifting laterally an osteoperiosteal graft and then with the electric saw going through the whole thickness of the bone into the medulla to secure the inlay element, all in one piece.

Displacement of Semilunar Carpal Bone.—J. D. Adams (*Journal of Bone and Joint Surgery,* July, 1925) states that a true dislocation of the semilunar carpal bone occurs only when it becomes extraarticular, namely, when its relationship with both the os magnum and radius has been completely disturbed. The persistent dorsal displacement of the midcarpal row produces a permanent disability in the wrist. In the early instances it may be restored to normal position, but if allowed to remain is extremely difficult, if not impossible, to cure. Closed reduction should be attempted only within forty-eight hours of the injury, and then with extreme caution as to traumatizing the flexor tendons and the articular surface of the carpal bone. Open reduction is attended with a great deal of danger of traumatizing the articular surface of the flexor tendons. The convalescence is long and the end results unsatisfactory. Removal of the bone should be done in all cases where dorsi and palmar flexion are limited to the extent of interfering with the patient's work. Early motion following operation should be emphasized. In cases where the interim between injury and operation does not permit of the closed reduction method and where the rotation on the radial articulation is not sufficient to cause displacement of the articulation with the os magnum, thus leaving a sufficient function in flexion and extension, the operator should carefully consider nontreatment.

TESTIMONY AS TO INJURY BASED PARTLY ON INFORMATION FROM OTHERS HELD INADMISSIBLE

In a personal injury case, a medical witness, who had examined the plaintiff for the purpose of qualifying as an expert witness as to her condition, after being asked whether he made any examination with reference to the then bladder condition of the child and answering in the negative, was asked whether he had at that time obtained a history of the case, and answered that he had, from the child's father and stepmother. He was then asked whether from the history so received and from the examination he made he could say whether or not there was a subsisting injury to the bladder. The New Jersey Supreme Court holds, Altieri v. Public Service Ry. Co., 128 Atl. 547, holds that the last question and the answer that there was such an injury, were improperly admitted, under the rule that the testimony of a medical expert as to the condition of a plaintiff, based partly on information received from third persons, is incompetent, where the expert has been employed to make an examination of the plaintiff solely for the purpose of qualifying him as a witness, and not for the purpose of treating the patient.

DEGREE OF SKILL IN DIAGNOSING FRACTURE

In a malpractice action for injuries received in the treatment of a dislocated arm, which defendant claimed to be a Colles fracture, there was much evidence tending to show that plantiff actually sustained a Colles fracture, but there was also evidence that the injury was a dislocation of the ulna. Defendant admitted that he did not discover the dislocation of the ulna if any, and the fact that it had broken loose from the radius. There was evidence that the treatment in either case would be different.

Reversing judgment for plaintiff, the Missouri Court of Appeals said, in part: "Of course, defendant was liable if he failed to use that degree of care and skill of the ordinary physician of similar localities in diagnosing or discovering the true condition of plaintiff's arm. But there should be some testimony tending to show that a physician of ordinary skill in the locality in question, and by the means at hand, could have discovered the dislocation differentiated between it and a Colles fracture; or whether or not a physician of such skill should have waited until the swelling subsided (if it would) before determining upon the character of the injury, or whether, if he was in the exercise of ordinary care in diagnosing the trouble as a Colles fracture under the circumstances, he should have made a further examination after the swelling had subsided."

RATIFICATION OF UNAUTHORIZED DEED BY HOSPITAL'S PRESIDENT

The Missouri Supreme Court holds, Josephine Hospital Corporation v. Modoc Realty Co., 270 S. W. 638, that the fact that the trustees of a hospital for a period of years left the entire management and control of the hospital and its property to its president, gave him no authority to convey its real estate without express authority from the trustees. Such a deed was not sufficient to bind the hospital and could have been set aside by timely and appropriate action on its part. But where the majority of the trustees knew of the deed and took no action to set it aside for twenty months after such knowledge was acquired, the rights of third parties having intervened, and the hospital having got the benefit of the proceeds of the sale, the hospital was held to be estopped by delay, neglect, and laches of its trustees to say that the deed was unauthorized and insufficient to convey the title of the hospital, and that the trustees had thereby ratified the deed.

LIABILITY FOR LEAVING SPONGES IN WOUND

The Arkansas Supreme Court holds, Spears v. McKinnon, 270 S. W. 524, that in an action against two physicians for malpractice for failing to remove a sponge from the abdominal cavity after an operation, one of the defendants could not claim exemption from liability on the ground that he was assisting the other defendant, who had not instructed him to search the abdomen for sponges after the operation, where the evidence showed that his part in the operation was to insert and withdraw the sponges. It was held that the defendant's liability was joint and not several, and a verdict of "$3,500 against Dr. S. and the sum of $3,500 against Dr. P." should have been followed by a joint judgment against defendants for $3,500 and not by a judgment for $7,000, one-half to be recovered from each defendant. The court applied to the facts of the case the rule that surgeons cannot relieve themselves from liability to a patient for injury caused by leaving a sponge in the wound after an operation by adopting a rule requiring the attending nurse to count the sponges used and removed and relying on such count as conclusive that all sponges have been accounted for.

QUALIFICATION OF EXPERT ON EFFECT OF STRYCHNINE

The Texas Court of Criminal Appeals holds, Hext v. State, that, in a prosecution for murder by poison, a physician may qualify as an expert witness as to the effect of strychnine poison on knowledge obtained from the study of books upon the subject without showing personal experience.

INSUFFICIENT EVIDENCE OF HOMICIDE

The Texas Court of Criminal Appeals holds, Vancel v. State, 272 S. W. 130, that in a prosecution for murdering a week old baby, the testimony of a physician was insufficient to sustain a conviction where it did not show whether the child died from some criminal means or agency or from natural causes. Mere motive and other circumstances pointing to one as being likely to commit a homicide are not sufficient to sustain a conviction.

CERTIFICATE OF DEATH EXCEEDING AUTHORITY OF STATUTE HELD INADMISSIBLE

The Mississippi Supreme Court, Massachusetts Protective Ass'n v. Cranford, 102 So. 171, holds that, in an action on an accident policy involving the issue of whether the insured committed suicide or met his death accidentally, a certificate of death issued by the bureau of vital statistics under Hemingway's Code, Sec. 4872, stating that the death was "suicidal," was not admissible, since the certificate should have merely stated that the cause of death was a gunshot wound. The authorized purpose of the certificate was to do no more than state the cause of the death, as by a gunshot wound as in this case, and not whether the wound was inflicted by any certain person, by assassination, by accident or by intentional selfdestruction. The court did not find it necessary to decide whether such certificates are ever admissible in such cases.

DEGREE OF CARE AND SKILL REQUIRED

The Vermont Supreme Court holds, Parker v. Bowen, 126 Atl. 522, that the standard by which the work of a physician charged with malpractice is to be judged is the care and skill usually exercised in like cases by physicians and surgeons in the same line of practice in that general neighborhood, and he is not to be judged by what a medical witness testifies he would have done in circumstances shown by the evidence.

On the Relations Between Physician and Patient

MAX EINHORN, M.D.
New York

INTRODUCTION

Physicians and patients come in contact with each other almost daily. There are questions arising on either side requiring elucidation. For this reason I may be permitted to sketch briefly my views on this topic.

MATTERS CONCERNING THE PHYSICIAN

While there is complete accord among physicians and surgeons with regard to the question as to what we should do for the patient, there is a great deal of discord as to what we should tell him.

The practitioner (physician and surgeon alike) is the custodian of his patient. He endeavors by all means known in medicine to restore health to the sick. He also tries assiduously to render incurable conditions more bearable, and to alleviate suffering. There is no controversy as to the duties of the medical profession with regard to its activity as given in the two preceding sentences.

The question, however, what we should tell a patient, presents a more difficult problem. It is self-understood that like all honest persons the physician also likes to tell the truth. There would be no question about it, if this would be feasible and not interfere with his duties toward the patient. But alas, the two items: "truth and welfare of patient" frequently conflict with each other and work in diametrically opposite directions.

Before deciding what is best to say it will be well first to state what the practitioners usually do. We shall then discuss the reasons for and against telling the truth and try to select the best way as it appears to us.

Some of our colleagues do not hesitate to tell a patient what he is suffering from, no matter what effect it will have on him. They maintain: "We must tell the truth, no matter what its consequences may be." Even in fatal diseases, they give their exact diagnosis to the patient. Aside from the disagreeable sensations and the great harm done to a patient who is told that he is going to die within six months or so, such a diagnosis and prognosis may, by chance, not be correct. For mistakes can happen, no matter how careful the practitioner is: *"Errare humanum est."* In such an instance the true opinion of the physician, which in reality was not even the truth, has sometimes done even irreparable harm to the patient, and has brought discredit to the physician besides.

Some colleagues say we must tell the truth in order not to delay operative intervention, if feasible. This, however, is not a sufficient excuse for causing the necessary hardships to the patient by the true verdict. For he can be informed of a necessary operation by other milder means. Thus, for instance, a patient with an operable carcinoma of the stomach may be told that he is troubled with a certain variety of gastric ulcer requiring surgical measures for a quick and efficient recovery. He will usually consent to a surgical operation without suffering the fright of cancer.

The other colleagues who tell the truth whenever it can be done without harm, but refrain from it in all other instances, maintain that they have to act in the interest of the patient. It contributes greatly to his welfare, if he is not aware of the truth. The latter is usually told to the immediate family, a near relative or a friend, as the case may be. Thus the approval of the family is obtained, the truth known, and the best done for the patient.

While everybody is entitled to his own opinion, the question comes up, which party appears to act more judiciously, so that we may generally recommend its procedure.

Before discussing whether the truth should be told the patient under any circumstances or not, I may be permitted to make a few general remarks.

The art of medicine consists principally in studying the natural phenomena of the living organism and in helping to carry out Nature's intent. Thus, food, water, and air have to be present in certain quantities to make life possible. If the physician discovers a deficiency in the items just mentioned he can at times remedy this shortcoming by supplanting it. He will in this way create new conditions for a successful continuation of life. In disease also Nature paves the way for recovery and the physician tries to carry out Nature's intent. At times medicine removes barriers against life, which Nature was not able to abolish, and makes life possible. As an instance we mention complete obstruction of the esophagus and its cure by gastrostomy, or severe cardiospasm and its treatment by overdilating the cardia. Death would have resulted from lack of food. The procedures mentioned remove the barriers

Copyright, 1926, by A. R. Elliott Publishing Company.

against the intake of food and make life possible according to Nature's requirements.

There is an innate desire to live in each organism. Even the aged and decrepit and the incurably diseased cling to life. Nature has provided us with this sensation in order to enjoy every minute of our existence. In times of sickness and suffering Nature frequently masks the real condition and imparts hope and a favorable outlook for the future. In a busy practice of over forty-one years I have seen but a few instances of moribund patients who were aware that they were going to die (amounting perhaps to one per cent.). The bulk of the dying patients, however, no matter what sickness they had gone through, acute or chronic, with great suffering or comparatively mild discomfort, are never aware of the coming end and die not knowingly. We come into the world without any knowledge of our existence and we leave it in the same manner.

This provision of Nature, not to let a living being know its coming end, we must carry out in like manner that we follow its laws and apply them diligently in the entire field of medicine.

In coming back to the original question, should a patient be told that his life is in danger or perhaps doomed? We must answer in the negative. For we physicians carry out Nature's intentions and follow its laws unremittingly. Everybody knows what harm can be done by one harsh disagreeable word, especially if it is true, and concerns life, the most valuable asset a living organism possesses. Not only must we try to dissimulate any idea of an approaching death, but we must also in other difficult situations always speak encouragingly to the patient. Anxiety and worry exert a depressing influence, while contentment and cheerfulness exert an exhilarating influence and pave the way for recovery where the latter is possible.

What if the patient asks directly for the truth? I personally would never give a death verdict to a patient, and would give hope and encouragement under all circumstances.

The physician treats his patient to the best of his knowledge and ability. If he thinks that in a special case more help can be obtained by expert advice he should inform his patient and suggest a consultation with the colleague he considers best fitted. Should the patient mention somebody else the physician should always accept his patient's suggestion. Everybody is master of his own life, and we have no right to interfere with the master's wishes. In the same way we may suggest an operation or some special method of treatment, but if the patient refuses to accept it, we may try and give our reasons for the suggestions, but we must accept and honor his opinion and treat him as best we can accordingly.

Any time the patient should desire to be treated by some other physician the attending physician should retire without any grudge, and should also resume the treatment in case the patient desires him to do so. The physician must put his own feelings in the matter in the background and act only in the interest of the patient.

MATTERS CONCERNING THE PATIENT

The custom of having a family physician has of late years been greatly interfered with, not always to the best advantage of the public. Now as in former times everybody should have his family physician. The latter should be his attendant and guardian in health and disease. In selecting a regular family physician honesty and conscientiousness play the leading role, ability the second. It cannot be expected that a physician can be an expert in all ailments. But the true physician—who looks after the patient with the same interest as he would like to be looked after himself—will know what to do when he notices his shortcoming. He will select additional help, whenever required. In order to obtain the best results the full confidence of the patient in the actions of the attending physician is an absolute necessity. The patient should endeavor to live up to the precepts of his advisor when well and especially so when sick.

Inasmuch as all the actions (words and deeds) of the family physician are calculated to do good, too much interference by the patient or the family is certainly not advisable. In case the patient or the family are in doubt whether the attending physician is on the right path, a consultation should be suggested and accepted by the physician in charge. If the confidence in the attending physician is not fully restored, it is better for the patient to select a new advisor. For with the lack of confidence no good will result either to the patient or to the physician.

The term of life not being known and a possibility of death always being present, it is desirable for everybody who has got a message to leave to posterity or any worldly goods to bestow to arrange that in writing in the form of a will, while yet in the best of health. From time to time such a will can be rewritten or additions made, as occasion demands. In this way nobody will be caught unprepared, and the good deeds planned during life, continued thereafter.

In conclusion, the following brief summary appears justifiable. By following the suggestions outlined, life will at times be prolonged and its enjoyment always enhanced. Thus a great boon will be conferred on the patient and much satisfaction, and a feeling of duty well fulfilled, bestowed on the physician.

20 East Sixty-third Street.

A Modified Mayo Umbilical Herniotomy.—C. A. Roeder (*Surgery, Gynecology and Obstetrics,* May, 1925) has devised a modification whereby the umbilicus may be saved, provided the umbilical hernia is not very large, the outline of the umbilicus not destroyed, or the abdominal wall not too fat. In this operation only one half the usual area of fascia is denuded of fat. This lessens the occurrence of postoperative fat emboli proportionately. For a varying length of time following the operation there is a palpable mass just beneath the remaining umbilicus which has been mistaken by examining physicians for a recurrence. This mass is the result of doubling of the abdominal layers which protrude the umbilicus just enough so that it is mistaken for a recurring hernia. This disappears in due time, however, leaving the region around the umbilicus with a normal appearance. The author says that he performed this operation eight times in the past five years with no recurrence to his knowledge.

Signs of Acute Proved Cases of Intracranial Hemorrhage in the Newborn*

A. S. MACLAIRE, M.D.
New York City

Intracranial hemorrhage in the newborn has been a recognized pathological condition since the time of Denis (1) in 1826. The few early writers on this subject as Denis (1), Billard (2) and Cruveilhier (3), have been entirely forgotten in their pioneer studies and it was not until the time of Little (4) that renewed vigor and interest had been somewhat engendered. Only after Little's (5) second paper has this condition become, what may be termed, a modern entity, namely, that physicians became aware of the existence of such a condition and yet, it was twenty-three years (6) before another important contribution in this field was received. The studies were still all of a postmortem nature. The clinical diagnostic acumen had not yet attained that degree of perfection whereby living patients suffering from intracranial hemorrhage at the time of birth could be diagnosed. It is reasonable to assume, since nothing had appeared in the literature until quite recently with reference to the clinical feature of this important condition, that the general feeling at that time must have been that all cases of intracranial hemorrhage in the newborn were necessarily fatal since clinical diagnoses were unknown. As we became more alert to the existence of intracranial hemorrhage in the newborn, diagnoses were being made in the late and moribund stages. This, however, was a step in advance since the clinical significance of what was formerly thought to be only a pathological entity was beginning to be recognized while the patient was still alive, even though death soon supervened. As evolution in any field is a slow process, so has the evolution of the recognition of the very mild and resuscitatable cases of intracranial hemorrhage in the newborn been a slow, tedious and much criticized process. Gradually, with the increase in the acuteness of diagnostic ability, physicians became more adept and more keenly alive and perfect towards detecting or rather suspecting early, mild cases of intracranial hemorrhage in these newborn babies.

During the past score of years individual case reports of the correct, early diagnosis of the less severe stages of this condition with the initial recovery of the life of the patient crept into the literature. Even though this was another great stride in the progress of the diagnostic evolution of this cranial birth trauma, yet it was felt that such cases were a rarity.

The obstetrician easily conceived how such craniocerebral accidents could occur in the difficult and prolonged labors, where perhaps instrumentation and directly applied mechanical forces and devices to a head were essential in the extraction, but to obtain such injuries in the socalled normal, uncomplicated deliveries, he viewed askance with doubt, suspicion, prejudice, contempt and ridicule. Still, it is laudable, enlightening and agreeably encouraging to note the conversion of the selfsame obstetricians who previously scorned, for they were the first to eradicate their own blemishes by permitting the study and the search for the truth.

Through the courtesy of Wilbur Ward, F. A. Dorman and C. G. Childs, Jr., all of New York, permission was obtained to conduct this research upon this subject at the obstetrical division of the City Hospital, Welfare Island, New York. At the outset it was the purpose of the investigators to determine solely the frequency of intracranial hemorrhage in the newborn. Thus with that intention in view, five hundred consecutive newborn babies were routinely lumbar punctured within the first forty-eight hours of life within forty-five hours. As our (8) studies progressed new facts and new findings presented themselves to us and many formerly established beliefs were destroyed and new ones created. Aside from the importance of the work itself, it was interesting to note that what was really considered as some of the most important factors in the production of intracranial hemorrhage in the newborn were in reality of little significance.

ETIOLOGY

It is the consensus of opinion of most workers in this field that the cause of intracranial hemorrhage in the newborn can be chiefly attributed to one of the following groups:

1. *Trauma.*—The traumatic group comprises those cases where the intracranial hemorrhage results from the mechanisms of labor. It need not necessarily be an abnormal factor in the delivery, as will be demonstrated later on, although this accident or complication is more likely to occur where the labor has been difficult due to some form of dystocia, whether it be maternal, fetal or placental in origin. The maternal contributions to dystocia that may lead to cerebral birth hemorrhage in the offspring are due to abnormalities in the uterine force and uterovaginal passage both of the bony as well as soft parts. In discussing uterine force we really refer to the character of the uterine contractions and the type of labor pains with their ultimate results. The fetal responsibilities are found in the disproportion between the size of the child and the birth canal, or in abnormal presentations where the head will of necessity be subjected to a prolonged and protracted labor with its concomitant results. Certain forms of placenta previa will act in the capacity of an obstructing agent and in this manner will lengthen the actual time of the delivery. The significance of this fact is that further moulding of the head is required before delivery can be completed and in some instances an interference with the fetal blood supply is produced which materially enhances the danger of a congestion which in itself is conducive to hemorrhagic extravasations.

*Delivered before the New York Physicians Association, November 25, 1925.

2. *Asphyxia.*—Increased congestion arising from whatever cause produces an increased intravascular tension as well as an increase in the asphyxia. The heightened pressure within the delicate vessels eventually produces a rupture followed by hemorrhage of varying degree.

3. *Hemorrhagic disease of the newborn.*—This condition, according to our findings on the coagulation of the blood, has been unduly overemphasized by the pathologist and pediatrist. In this series only one case had a prolonged coagulation time, namely ten minutes. It may be, however, that sufficient time had not been permitted for the condition to display itself in the legthening of the coagulation time as all these blood readings were done within the first forty-eight hours and Rodda (9) states that the prolongation in the clotting time does not appear before the third day, except in some instances where it is present as early as the sixth hour. Conkey (10) also is inclined to feel that the hemorrhagic disease theory has been overstressed to the exclusion of the obstetrical factors.

4. *Syphilis.*—Lues is usually an accommodating and innocent disease and often acts as a screen behind which ignorance at times can be successfully shielded and protected, since the Wassermann reaction is not entirely infallible in its results and an error of correction is possible in a certain percentage of negative reports; thus, one can still maintain and cling to the diagnosis of syphilis in spite of all the evidence to the contrary. This disease has been accused of being the etiological factor in the production of most diseases in medicine and so has it been accorded its prominence in this condition from time immemorial. These studies fail to substantiate that most fallacious and ancient supposition and contention, for in only six cases out of the entire forty-five bloody ones or 13.33 per cent. was syphilis present either in the mother or child. Yet, it can not be stated with absolute certainty that syphilis was the sole responsible factor in more than two out of these six cases, as the intracranial hemorrhage could have occurred as the result of the type of labor. The significance of this statement will be obvious later on. The labors in these six cases were as follows: Two medium forcep applications, one breech, one right occipitoposterior position, one low forcep application, and one left occipitoanterior position. Of these six luetic children, four were white and two were colored. As to race in this hemorrhagic series of forty-five cases, twenty-seven were white, or sixty per cent. and eighteen or forty per cent. were colored. Syphilis, therefore, occurred in 14.81 per cent. of the whites and 11.11 per cent. of the colored. The common conception that syphilis is more prevalent in the colored race can not be supported by this work. The significance of these findings merely confirms the impression insinuated above that as a causative factor in the production of intracranial hemorrhage in the newborn, syphilis plays but a minor role.

Race (total)		*Positive Wassermann (total 6 cases)*	
White	*Colored*	*White*	*Colored*
27	18	4	2
or	or	or	or
60 per cent.	40 per cent	14.81 per cent.	11.11 per cent.

5. *Pituitrin.*—This powerful oxytocic drug has been regarded by Ehrenfest (11), Lippman (12), Sidbury (13), Neff (14), and Porter (15), as an important factor in the production of intracranial hemorrhage in the newborn. Conkey (10) supports Ehrenfest (11), in the belief that vigorous methods of resuscitation aggravate and increase the size and signs of dormant and concealed intracranial bloody extravasations.

FREQUENCY OF HEMORRHAGE IN THE VARYING TYPES OF LABOR

In a series of five hundred consecutive newborn babies a routine diagnostic lumbar puncture was performed within the first forty-eight hours after birth. It was indeed a great surprise when it was learned that forty-five babies or nine per cent. of the series contained blood or blood elements in varying degree in the spinal fluid. The clinical pictures in these forty-five cases varied markedly in most instances; in some, bloody cerebrospinal fluid was the only indicator of the intracranial lesion, whereas in others, the clinical signs were manifested on a sliding scale ranging from those mild and easily overlooked to those which very obviously pointed to cerebral irritation. The type of labor played a most important part in the etiology of the production of the intracranial trauma. A short résumé of the different types of labor which occurred in this particular series with its corresponding percentages of intracranial hemorrhage is most enlightening and startling as well as interesting and significant.

Of 395 normal deliveries, i. e., left occipitoanterior and right occipitoposterior position, only twenty-two cases or 5.56 per cent. disclosed bloody cerebrospinal fluid of some degree. Another extremely important feature which destroyed one of the solid pristine beliefs was the observation that only three out of forty-three cases of properly applied low forceps showed evidence of blood in the cerebrospinal fluid at lumbar puncture. The percentage in this group was 6.97 per cent., only 1.41 per cent. greater than the most easy and normal method of delivery. The results of medium forcep applications were more striking but not entirely unexpected or unwarranted from such a procedure; 100 per cent. bloody fluid was displayed at spinal puncture. There were four cases in all. Only two cases represented right occipitoposterior position and of those 1 or 50 per cent. had bloody spinal fluid.

This perhaps would be more expected or anticipated as the degree of moulding must of necessity be greater and the uterine contractile forces more powerful to overcome the disadvantageous position of the fetus. Precipitate labor has always held its attraction for both doctor and patient and was considered a most welcome procedure; the mother was soon rid of her pain and suffering while the physician escaped the long tedious hours of waiting. Yet in our series 25 per cent. (two out of eight cases) of the children had been traumatized by an intracranial hemorrhage. Premature delivery, aside from the danger of incomplete development of the individual, subjects an unfinished product of conception to greater risks of trauma since the unprepared body must be ready to combat the same forces and withstand the same vicissitudes of nature as the normally developed one. Four out of eleven babies or

36.36 per cent. gave evidence of bloody spinal fluid at the lumbar site. Of twelve breach deliveries, three or 25 per cent. had bloody intradural fluid. In thirteen cases of prolonged labor four or 30.76 per cent. were found with the intracranial complication of hemorrhage. In three dry labors, in four cases of face presention and four cases of eclampsia or pre-eclamptic state, there was one case in each group that had bloody intrathecal fluid. The percentages were respectively 33.33, 25 and 25 per cent. In one case of Cæsarean section, one case of induced labor and seven cases in which the presention was not mentioned, the cerebrospinal fluids were normal. A fact of great importance noted in this series was the finding of clear fluid in all three cases of stillborn babies.

Type of Labor.	*No. of Cases.*	*No. of Hemorrhages.*	*Per-centages.*
Normal labor (left occipitoanterior and right occipitoanterior	395	22	5.56
Low forceps	43	3	6.97
Medium forceps	4	4	100.00
Right occipitoanterior	2	1	50.00
Precipitate	8	2	25.00
Breech	12	3	25.00
Premature	11	4	36.36
Prolonged	13	4	30.76
Dry	3	1	33.33
Face	4	1	25.00
Eclampsia or preeclampsia	4	1	25.00
Cæsarean section	1	0	
Not mentioned	7	0	
Induced labor	1	0	
Stillborn	3	0	

In these forty-five proved hemorrhagic cases an initial mortality of four or 8.88 per cent. was present. Postmortem examinations in three cases revealed extensive supracortical hemorrhage in one case, ventricular hemorrhage in another and supracortical, basal, ventricular and spinal in a third and autopsy was refused in the fourth.

SIGNS IN OUR CASES

The paucity of signs in this condition makes it very difficult at times to diagnose with any degree of surety many of the milder cases of intracranial hemorrhage in the newborn. On the other hand, neither does the presence of signs always signify the existence of an intracranial bloody extravasation. In this series a total of thirty-five signs were observed in eighteen patients or 40 per cent. of the total number, the other twenty-seven patients with hemorrhage or 60 per cent., failed to evince any indication of an intracranial complication and would have been overlooked in all probability if a routine lumbar puncture had not been performed. Whether any resultant defects would have occurred in any of these latter twenty-seven cases if the pathology had not been discovered is a question which is unanswerable satisfactorily at present, for no doubt many mild cases of intracranial hemorrhage grow up without any abnormalities, the blood having been absorbed completely. To be able to determine in advance which case will require lumbar drainage or even cranial drainage and which case will take care of its own hemorrhage is a difficult problem. All that can be offered at present from past experiences is a formulated plan, which has been adopted for the present and is subject to change depending upon the individual case, when cranial drainage should supersede lumbar drainage; but to differentiate cases which require spinal drainage from those which require no drainage at all is at present impossible. Thus, until our prognostic ability becomes so highly developed and perfected as to be capable of selecting or separating those cases which require treatment from those cases where Nature's own methods are sufficient to absorb the blood without the danger of any residual impairment, it is more advisable to drain by repeated lumbar punctures all cases showing bloody cerebrospinal fluid until the fluid becomes clear.

The signs which are to be discussed in this paper occurred within the first forty-eight hours of life and were chiefly in the milder types of cases. That this condition in the newborn is of utmost importance, we need only refer to the recent opinions of Schwartz of Berlin (16) and Fischer of Basle (17). The former stated that intracranial birth injuries completely dominated the pathology of the first month of life and the latter author placed the responsibility of cerebral birth trauma as the cause of ten per cent. of the deaths during the first month of life: and those were the reports of pathological studies. How many more cases of milder degree escape unnoticed, such that could produce the varying forms of plegias, as diplegia, hemiplegia and paraplegia with or without mental deficiency?

The most frequently observed sign in this series was twitchings of the hand. That occurred in five cases or 27.77 per cent. Twitchings of the feet were noted in four instances or 22.22 per cent. Cyanosis, poor nursing, convulsions, unusual drowsiness were each present three times or 16.66 per cent. Rigidity of the extremities, jaundice and respiratory difficulties were recorded as each being present twice or 11.11 per cent. Twitching of the mouth and face, epistaxis, a weak cry, vomiting, frothing at the mouth, failure to cry and supranuclear facial palsy were each present once or 5.55 per cent. The intracranial pressure as determined by the spinal mercurial manometer (18) was increased in twenty-six or 57.77 per cent. The bulging or tense anterior fontanelle was not found to be a reliable indicator of the existing intracranial pressure, for in only five cases did the increased manometric reading verify and substantiate the condition inferred from the state of the anterior fontanelle.

Capon (19), in a clinical study of cases which eventually came to autopsy, recorded such signs as oral pallor, nystagmus, ocular palsies, pupillary inequalities, myosis, ptosis, yawning, sighing, automatic muscular movements i.e., alternate closing and opening of the eyelids, exaggerated reflexes, erection of the penis and wrinkling of the scotal skin as additional signs to some of those enumerated above by us. His cases, however, were all fatal, whereas we dealt almost exclusively, with the exception of four cases, with the milder type of intracranial hemorrhage which survived either as a result of the repeated lumber drainage or would have recovered anyway as far as life is concerned.

DIAGNOSIS

Whenever a newborn baby shows any one or a combination of any of the mentioned signs, and

particularly so if they should follow a type of labor where the percentage of intracranial hemorrhage in the newborn as a complication is relatively high, it is advisable to perform a lumbar puncture for diagnostic purposes. A word about this procedure may not be amiss.

There is practically no danger entailed in the performance of this test if certain few rules are adhered to. The first and most important one is always to remember never to do a lumbar puncture if the patient is in shock, for whatever information may be derived from the findings of the spinal fluid, it is not going to be of any material clinical assistance as far as therapeutics are concerned, if the baby is unable to overcome its shock. The added trauma of spinal puncture, however slight, will certainly not decrease the shock. After that period of depression is over, then resort to this diagnostic means. To perform a lumbar puncture in a newborn baby is not as simple as it may appear, yet after a certain amount of experience it becomes almost as easy as in the adult. A great deal of the success in entering the vertebral canal depends upon the degree of flexion of the spinal column obtained by the aiding nurse. Once the technic is mastered the rest of the difficulties are overcome.

If a cerebral hemorrhage has been discovered then spinal drainage can be immediately instituted and repeated according to the severity of the extravasation. The finding of clear spinal fluid in a small percentage of cases, similar to a negative Wassermann, does not entirely eliminate intracranial hemorrhage. I have had that experience twice, once in an acute case and once in a chronic one.

I was asked to perform a lumbar puncture upon an acute case with the following history: The baby, born May 26, 1925, at 3 a. m., at the Nursery and Childs Hospital, was a case of prolonged labor with eventual breech extraction. The resuscitation was difficult, although no heroic measures were taken and asphyxia pallida was present. At 8 a. m. that same day, general convulsive twitches were observed, the eyes were held open, the child was in a stupor and unable to nurse. This continued all day. On the 29th, at 9 a. m., three days later, the condition had become markedly worse so that Cheyne-Stokes respirations were noted and the respirations at times ceased entirely; the cardiac beat was almost imperceptible. Two hours later, i.e., at 11 a. m., that day, I did a lumbar puncture on a child who was fairly cyanotic and whose body was cool. It did not require much diagnostic ingenuity to make a diagnosis of intracranial hemorrhage in that particular case. Yet, how amazed we all were when the spinal fluid at the lumbar site was clear and not under pressure! The child died and at autopsy an intracranial hemorrhage was found, the source of the bleeding having arisen from a laceration of the marginal sinus.

Another instance was that of a chronic case at which I assisted at the operation. That baby had had a lumbar puncture performed on the third day by the doctor who referred the case and who had obtained clear cerebrospinal fluid. The operative pathology was that of a residue of a former intracranial hemorrhage with increased intracranial pressure.

Thus, one can state with a fair degree of assurance that, with the exception of a small percentage, clear cerebrospinal fluid obtained at lumbar puncture in a case suspected of possessing an intracranial hemorrhage eliminates that possibility from further consideration.

TREATMENT

The treatment consists of repeated lumbar punctures every six to twenty-four hours until clear cerebrospinal fluid is obtained depending upon the degree of severity of the hemorrhage, i.e., the greater the percentage composition of blood in the cerebrospinal fluid the oftener the lumbar puncture must be repeated. If within three or four days of such treatment, the character of the cerebrospinal fluid remains unaltered, or it appears that little or no benefit is being derived from lumbar drainage, then cranial drainage must be instituted.

The follow up work in these City Hospital cases is very unsatisfactory as cooperation is very poor on the part of the parent, but every effort is being made to secure the present status of each child. Thus far about eight mothers have responded to our letters and of those one child died in a hospital from which we are endeavoring to secure the cause of death as well as the physical and mental state of the child at the time of admission to that hospital. The other seven children are perfectly normal with the exception of one, two years old, that has not made much progress in speech outside of uttering ma-ma and pa-pa.

SEQUELÆ

Improperly or insufficiently treated cases may result in the varying forms of spastic paralysis with or without mental impairment ranging from simple retardation to idiocy associated with or without epilepsy. Another sequel recently discovered by the author and discussed (20) elsewhere in detail is that of hydrocephalus either of the communicating or complete internal types. The case responsible for the discovery was that of a severe intracranial hemorrhage seen six hours after birth and at which time a fatal prognosis was given. With the aid of repeated lumbar puctures the child however survived, but the entire hemorrhage had not been drained off. The clinical picture was so favorable at the end of the fourth day that the advice to institute cranial drainage was not accepted. At the end of one month the child was considered quite normal by the pediatrist. At the end of the second month the child had a typical communicating hydrocephalus with an enlarged head, separated cranial sutures, increased intracranial pressure, the anterior and posterior fontanelles enlarged and communicating.

SUMMARY

In summing up the clinical situation of this condition, it may be said that whenever any of the signs referable to intracranial hemorrhage, no matter how mild the case may be, make their appearance and especially so if the labor has been at all conducive towards the production of intracranial hemorrhage, a lumbar puncture for diagnostic purposes should be performed. If hemorrhage is present, repeated spinal drainage should be attempted without any further loss of time. If that treatment is insufficient

cranial drainage must be resorted to in order to prevent any of the sequelæ that are possible.

The Soft Palate as a Place for Signs of Disease*

PAUL NEUDA, M.D.
Vienna, Austria

Several years ago, four parallel series of observations were the occasion for attributing a special symptomatology to the soft palate and for closer observation.

1. In line with certain erythremic conditions, it was observed that the number of erythrocytes did not by any means run parallel with the erythremic discoloration of the soft palate. On the contrary, more frequently than could be ascribed to an accident, there was found a considerable red discoloration of the soft palate without the presence of a large number of red cells in the peripheral blood, and, inversely, a not very marked red discoloration with a strikingly high erythrocyte count. Furthermore, it was also demonstrable that it was mainly the soft palate and positively not the rest of the oral mucous membrane, which showed striking changes even with slight conditions of erythremia.

2. Cases of icterus, observed continuously especially in parenchymatous disease of the liver, showed that the soft palate alone and on the very site where it joined the hard palate, contained the pigment for the longest time, and even that the yellow discoloration became still more intense at this site in the course of time.

3. Cases of duodenal ulcer not infrequently showed a true and even considerable polycythemia. Such a polycythemia in duodenal ulcer has previously been observed by G. A. Friedman (1). As a result of the red discoloration, which was sharply limited by the hard palate, the soft palate in every case showed a very slight polycythemia. An entirely new feature, however, was the fact that the soft palate showed an erythremic discoloration without a demonstrable evidence of an increase in the red blood cells. It was therefore assumed as probable that the duodenal ulcer was associated with an increased amount of blood only in certain portions of the intestinal tract, being especially recognizable in the soft palate.

4. In cases of pancreatic disease (inflammation, necrosis) there was observed a characteristic bronze discoloration, which was entirely different from the usual yellow discoloration in liver and gallbladder diseases.

These observations led to the investigation of the recognizable characteristics (with the naked eye) of the mucosa of the soft palate. It was found that special attention must be paid to the following features: 1, the color; 2, the amount of blood present; 3, the water fat content, and 4, the marking. As a result of these experiences characteristic changes were recognized in a number of disease pictures especially cited later on. The significant feature of them all was the fact that they were all disease conditions in the intestinal tract or its accessory glands (liver and pancreas). This fact undoubtedly demanded a special explanation. Such an attempt will be mentioned later.

A number of selected cases (sixty-five in all) were carefully examined in order to determine the most characteristic findings in the soft palate. The disease pictures were the following:

A. Icterus: In fact, this is not a disease, but only a symptom, nevertheless it is advisable to call attention to the most characteristic discoloration in this condition, namely, the yellow color of the soft palate (like all changes, most distinct at the angles on each of the raphé at the border of the hard palate). Certain differences were found in regard to the etiology and pathogenesis of the disease that leads to the icterus: Catarrhal icterus shows the least and the least permanent changes; the icterus of gallbladder disease or occlusion of the biliary passages shows a distinct and sometimes intensive yellow color, but this is confined to the angles; the most extensive changes are seen in icterus due to a parenchymatous disease of the liver, in which the yellow color begins to tinge the soft palate diffusely. In such a case a fatty infiltration of the soft palate is also demonstrable. These changes appear even without

*Read before the Association for the Diseases of Digestion and Metabolism, Vienna, October 3, 1925.

the development of a general icterus. The importance of these changes was evident especially in diseases of the gallbladder, then diseases of the liver in the course of syphilis and in intrafetal disease of the liver in very young infants.

B. In acute pancreatitis there was a most characteristic bronze discoloration, with the same localization as the yellow. With the aid of this symptom the diagnosis was established in three indefinite cases, and in one case the previously made probable diagnosis of acute pancreatitis was corrected by the absence of this symptom. All of these diagnoses were verified at necropsy.

C. In duodenal ulcer the hyperemia of the soft palate (even without peripheral polyglobulia) served as a common and good differential sign against gastric ulcer. The latter just like the peptic ulcer of the jejunum, and appendicitis, showed a nonhyperemic and, on the contrary, a more or less pale soft palate.

The explanation is based upon embryological facts. The ectodermal and entodermal folds meet somewhere in the mouth. Their point of union lies in the plane that runs anteroposteriorly and from below upward and cuts the roof of the mouth somewhere in this manner. The fact that all of the diseases mentioned affect the intestinal tract and its accessory glands leads to the probable conclusion that the borderline between the hard and soft palate is identical with the borderline between the ectodermal and entodermal folds. Accordingly, the soft palate is to be considered as entodermal and its changes in the changes of the intestinal tract might be based upon their relationship.

The External Respiratory Mechanism in Injury and Disease

JOSEPH BYRNE, A.M., M.D., LL.D.
New York

With the light that has come through recent researches the external respiratory mechanism renews its bid for the attention of the clinician. By means of transections of the brain stem Lumsden (1, 2, 3) has been able to differentiate at least three subdivisions of the respiratory centre, viz.: 1, the gasping centre situated caudad of the striæ acusticæ; 2, the apneustic (inspiratory) centre at the level of the striæ acusticæ, and 3, the pneumotaxic (expiratory) centre in the upper pons. Each of these centres mediates a distinct type of respiration, viz.: 1, the gasping type in which inspiration and expiration are of short duration with a long post expiratory period of rest; 2, the inspiratory type in which prolonged inspirations (apneuses) occur the muscles of inspiration remaining contracted at the height of inspiration; 3, the type with prolonged inspiration and expiration as observed after double vagotomy. The gasping centre is stimulated by lack of oxygen and by vagotomy and the apneustic centre by excess of carbondioxide and by lack of oxygen. Severe lack of oxygen may cause failure of tonic apneusis and induce gasping. Vagus stimulation acts as a depressant and also inhibits tonic apneusis. The pneumotaxic centre is stimulated by excess of carbondioxide, the presence of oxygen acting only as a depressant and tending, when in excess, to impair the vitality of the centre. Vagus stimulation inhibits the pneumotaxic (expiratory) centre. It also inhibits apneusis. Vagotomy releases and prolongs active expiration. The foregoing statements taken from Lumsden's papers have in the main been verified in my experimental work upon this subject done with intermissions, at Fordham University during a period of fourteen years. The succeeding remarks are by way of introduction to the clinical utilization of the laboratory findings.

The centres at the different levels evidently constitute an ascending, integrating series. In all such integrations each member of the series partially inhibits the member immediately below it and at the same time imposes its own, more differentiated form of functioning upon the active remnant of the more primitive mechanism. In this way each higher member rids itself by inhibition of what is cumbersome or useless in the more primitive mechanism while retaining what is essential and cooperative. In the lowest of the experimental series, i. e., in the gasping centre—activation is mainly chemical as opposed to reflex. The neural elements involved act merely as conductors, the musculature innervated by them executing movements akin to the most primitive form of respiratocirculatory movements, viz., sequential, active, thoracoabdominal systole and diastole. In the highest of the series, i. e., in the pneumotaxic (expiratory) centre activation is both chemical and reflex but under ordinary conditions is preponderately reflex.

In the intermediate member of the series, i. e., in the apneustic (inspiratory) centre, activation is both chemical and reflex. In the normal animal all the centres are activated both chemically and neurally the lowest centre acting preponderately under chemical and the highest centre preponderately under reflex influence. In the intermediate centre the chemical and neural factors are more evenly balanced. All this merely implies that the centres are autochthonous (automatic) in so far as they are under chemical dominance and reflex in so far as they are under neural dominance, the series as a whole acting in the normal animal, when not interfered with by voluntary impulses, under the dominance of the predominantly reflex highest centre. Of clinical significance is the experimental differentiation of the highest (expiratory) centre and from the intermediate (inspiratory) centre since it not only verifies the observations of clinicians of an earlier day but also inspires those of the present day and supplies them with the means for more intensive observation of respiratory phenomena at the bedside.

CLINICAL APPLICATION

In the respiratory centres, as elsewhere, the higher, more differentiated mechanisms are less resistant to nocuous influence than the lower more primitive mechanisms. Hence when both sets of mechanisms are exposed to cumulative, deleterious effects the more differentiated mechanisms are the first to succumb and in case of recovery the last to resume full function. In accordance with this fundamental biological law I have found clinically, in both animals and men, that in the vast majority of cases of approaching death from illness the expiratory is the first centre to succumb. In laboratory animals after injudicious administration of ether the respiratory mechanism frequently halts at the height of inspiration (tonic apneusis) and all that is necessary to set it going again is to make artificial expiratory movements by manual compression of the chest. After each act of compression an act of inspiration immediately ensues in such a manner as to leave little doubt that the chest compression was its immediate excitant. If, however, the anesthesia be deeper the inspiratory centre may also be paralyzed and now the mere compression of the chest is not of itself sufficient to induce an immediate inspiration although each act of vigorous chest compression is always attended by a recoil inspiration which may be sufficient to maintain the vitality of the inspiratory and expiratory centres until these resume their function. Compare the Schafer method of artificial respiration. These conditions are of course to be distinguished from the respiratory failure in sudden inhibition deaths which occurred so frequently in the early days of chloroform and ether when the technic of their administration was not so well understood.

Of importance to the clinician is the *early recognition of beginning fatigue or failure of the expiratory centre* in acute or subacute illness and in the exacerbations of chronic disorders. The first indication of this is the apparent stress under which this centre begins to function as contrasted with the ease and quiet under which it functions normally. This stress is characterized by a prolonged, forced, active, one might say tonic, expiratory act in which the breath is expelled in a prolonged, more or less audible puff which is cut short by a sudden, quick, more or less exaggerated inspiration (with dilated nares) at the expense of the normal postexpiratory rest period. In this form of expiration the thoracic and abdominal musculature is palpably and visibly brought into play to effect thoracoabdominal systole. This prolonged, active expiration represents the attempt on the part of the expiratory mechanism to get rid of poisonous substances such as carbon dioxide, etc., which act as stimulants of the inspiratory and expiratory centres. It is identical with the "blowing off" of the physiologists, the puffy respiration observed by clinicians in conditions like uremia, and is a component at least in the prolonged expiration so long and justly regarded by clinicians with concern in cases of suspected subacute or chronic pulmonary disease. It may be observed at certain stages in almost any form of disease associated with chemical poisoning of the central nervous mechanism, e. g., diabetes, opium poisoning, etc., or in cases of mechanical interference with the respiratory mechanisms, e. g., increased intracranial pressure, etc. At almost any death bed it may be seen before the lapse into the gasping stage. In this latter, short, sudden, inspiratory and expiratory movements are made the mouth and nares opening widely and the larynx working towards the chest with each thoracoabdominal diastole (inspiration) reverse movements accompanying each thoracoabdominal systole (expiration). In gasping a long rest period follows expiration. As the precursor of death the gasping stage has naturally had at all times much interest for the clinician and so more or less detailed descriptions of it with observations as to its prognostic import have been handed down from the earliest periods of recorded medicine.

CLINICAL METHODS OF STUDYING THE RESPIRATION

Up to the present time respiratory derangements incidental to disease or injury have received but scant attention the observations recorded in the clinical notes and charts being for the most part but casual and superficial. Thus one finds recorded perhaps the rate and depth of the inspirations, or the Cheyne-Stokes type of respiration, or some modification of it; or the grunting respiration found in chest injuries and in certain types of pneumonia or pleurisy; or the slow respiration of opium poisoning, etc. But the clinician had to be satisfied with the mere recording of signs without making any attempt at mechanistic interpretation and consequently without recognition of the true import of the disturbances observed.

Alterations in respiratory rate and depth are of service in helping to differentiate for instance acute affections of the respiratory system from those located elsewhere in the body, an increased respiratory rate pointing generally to a lung affection (pneumonia, etc.) and a normal or subnormal rate in the presence of high fever pointing to disease elsewhere, e. g., acute otitis media and other conditions. Cheyne-Stokes respiration, like gasping, though easily recognized is usually a preterminal condition and more or less hopeless from the therapeutic viewpoint. The grunting respiration of pneumonia is chiefly the result of insufficient aeration the grunting being nothing more than forced active expiration to get rid of the excess of carbon dioxide which stimulates the inspiratory centre and indirectly induces pain. By inspection alone one may estimate the rate of the respiration and the relative duration of each of the respiratory phases.

It is preferable, however, wherever possible, to use a stop watch to count the respirations and to measure the duration of each of its component phases, viz., inspiratory, expiratory, and rest period. Thus, as I pointed out some years ago (4), one can fairly accurately measure the lapse of time, e. g., 1, from the beginning of inspiration to the beginning of expiration; 2, from the beginning of expiration to the beginning of inspiration; 3, the period of rest. One may measure from any starting to any suitable stopping point the object being to determine the duration of each phase. It only takes a few minutes to take the times from which one may obtain the average duration of each of the phases. The measurements can best be made by covering the patient's eyes, the physician sitting at the bedside and observing in a suitable, not too bright light, the movements of the exposed chest and abdomen. In cases

of active forced expiration the thoracoabdominal musculature may be seen and felt in active contraction. Another useful method is that of recording separately upon a revolving drum the movements of the chest and abdomen by a suitable arrangement of writing levers and a time marker. In Fig. 1 is shown a set of respiratory curves taken from a cat after transection of the brain stem just cephalad of the pons. The expiratory centre is intact but is working somewhat under stress. These tracings, which somewhat resemble those taken with the Marey pneumograph were made by levers attached by means of a simple device outside of the chest and abdomen.

A similar contrivance has been used clinically by me but it has no advantage over inspection and measurement by the stop watch, except for purposes of demonstration, etc. The upper curve represents the abdominal and the lower the thoracic movements. Time seconds. The up stroke (expiration) shows a prolonged expiratory phase during the greater part of which the thoracoabdominal muscles were seen and felt to be actively contracting. By the stop watch the average of the times caught were as follows: 1, From the beginning to the end of expiration 8.4 seconds; 2, from the beginning of inspiration to the beginning of expiration 1.8 seconds; 3, rest period 0.6 seconds. Normally inspiration in man is set down by physiologists as of shorter duration than expiration. The ratio given, e. g., by Starling (5), Foster (6) and by Brubaker (7) is 10:12. Foster, however, takes care to say that expiration includes "such a pause as may exist," whereas Starling while giving the same inspiration-expiration ratio of 10:12 as Foster, admits a post expiratory rest period with a duration of about one third to one fifth of the total respiratory cycle. It must be kept in mind that these statements are based on tracings made by means of the Marey pneumograph which, in common with all similar instruments used in the graphic method, has the great defect of being unable to distinguish between active and passive movements. This difficulty is successfully met by the method devised by Head (8) in which tracings are directly taken from the anterior, tendinous portions of the diaphragm. These tracings show clearly that expiration is distinctly of shorter duration than inspiration with a rest period which has about twice the duration of inspiration and expiration combined. Head's method, however, does not record active expiratory movements.

For many years I have been seeking a satisfactory method of recording active expiratory movements with but little success. Some adaptation of Einthoven's string galvanometer seems to offer the only hope of solving the difficulty. For the present it must be said that by means of the clinical methods suggested by the author a much more correct estimate may be had of the active factors in respiration than by any of the graphic methods. In the pneumographs reproduced by Starling (5), Foster (6), and Brubaker (7), taken by means of the Marey instrument, there seems to be no rest period. But any one by means of a stop watch can easily measure a considerable period of rest in his own respiration or in that of other normal individuals; and in cases exhibiting prolonged forced active expiration one can see and feel the thoracoabdominal muscles in active contraction. The following figures represent the average duration of the respiratory cycle and of its different phases taken upon an average normal man:

From beginning of inspiration to beginning of expiration	3.48 sec.
From beginning of inspiration to beginning of expiration	.68 sec.
From beginning of expiration to end of expiration	.08 sec.
Rest period	.25 sec.

The total time for the separate phases is somewhat greater than the time for the respiratory cycle.

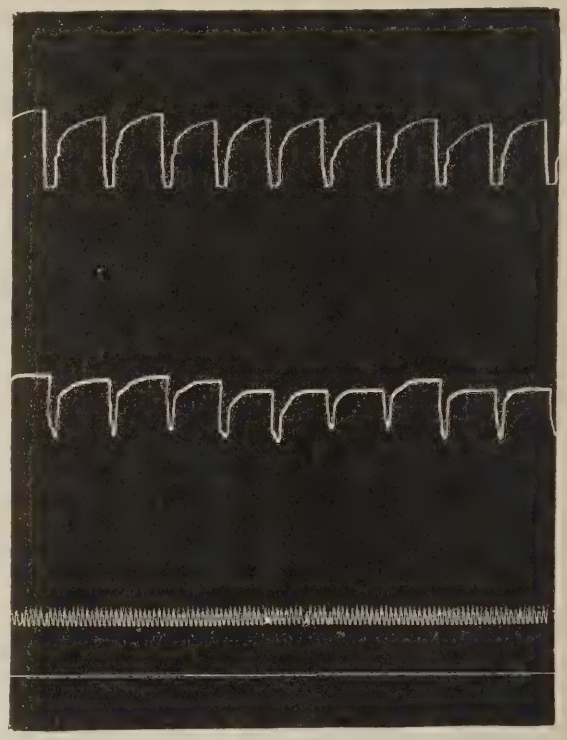

Fig. 1.—Prolonged active (fatigued) expiratory phase; partial apneusis from cat with brainstem transected just cephalad of pons; upper curve, abdominal; lower curve, thoracic movements; down stroke, inspiration; time seconds.

The difference is due to the time necessarily lost in starting and stopping the watch.

In diagnosis I have found analytical study of the respiration of service in the following conditions:

1. *Increased intracranial pressure.*—This is due to neoplasm, arterial hemorrhage, whether spontaneous or traumatic, edema cerebri or edema of repair caused by mechanical, toxic, or toxic infective trauma, increased secretion or diminished absorption of cerebrospinal fluid, etc. In any of these conditions prolonged forced expiratory phase may be detected long before the onset of the blood vascular and ocular phenomena set down in the textbooks as pathognomonic. On this account, from the viewpoint of diagnosis and therapy, analytical study of the respiration is of vital importance.

2. *Diseases of the heart and lungs.*—Any condition which interferes with the proper aeration of the blood thereby causing an accumulation of carbon dioxide in addition to lack of oxygen induces hyperactivity of the expiratory and inspiratory centres with early distress and exhaustion of the expiratory centre. In pulmonary conditions such as pneumonia, fibrosis, neoplasms and in pleuritic exudates, transu-

dates, etc., prolonged forced expiratory phase is early in evidence especially upon exertion. In cardiac disease this sign is elicitable quite early by having the patient perform light exercise. In asthmatic conditions whether of the cardiac or bronchial type the phenomenon is plainly in evidence. In suspected acute diseases of the lung the sign is invaluable in differentiating these from acute suppurative lesions elsewhere, e. g., in middle ear, etc.

3. *In disorders of metabolism.*—The study of the internal respiration (basal metabolism, etc.) has already more than justified itself. At the bedside, however, the clinician can no longer afford to overlook any diagnostic and therapeutic aid derived from analytical study of the external respiration. In conditions associated with acidosis prolonged forced expiratory phase is always in evidence and must ever be regarded as an ominous sign if the cause of the acidosis is not quickly removable. I have observed the sign in animals after removal of the pancreas and in patients suffering from diabetes. In one case, seen many years ago in consultation, the patient had just recovered from lobar pneumonia and the marked forced expiratory phase in the absence of fever and physical signs of consolidation, pleuritic exudate, etc., drew attention in the direction of a hitherto unsuspected diabetes. The family doctor had been misled by the fact that during the fever period of the acute chest condition there was no evidence of sugar in the urine. In uremic poisoning incidental to chronic kidney disease prolonged forced expiratory phase has been long familiar to clinicians. The sign, however, may be elicited in mild or latent uremia in the earlier stages when preventive therapy may be of lasting service.

4. *In poisoning* such as from opium, alcohol, ether, and other drugs prolonged forced expiratory phase is a prominent sign in the early stages.

THERAPY

In therapy analytical study of the respiration as set forth in this short communication has practical significance which cannot be overlooked.

1. *Oxygen administration.*—The presence of prolonged forced expiratory phase is a contraindication to the use of oxygen. This of course does not prohibit the use of oxygen but it implies that the oxygen must be diluted with air and that, if administered at all, the oxygen air mixture must be given intermittently. As previously stated prolonged, forced, active, expiration indicates an overworking pneumotaxic (expiratory) centre which is stimulated by carbon dioxide but depressed and vitally impaired by oxygen. The real therapy here would be the substitution of mechanical aids (rhythmic chest compression by hand or by other suitable mechanical apparatus such as that devised by me) to sustain or replace temporarily the overworking expiratory centre which otherwise must soon cease to function from exhaustion. In laboratory animals as well as in practice I have found this to be a remarkably efficient means for sustaining life and for resuscitation (e. g., after drowning, coal gas, ether, surgical shock, etc.), more especially when used in conjunction with rhythmic alternations of posture to remove by gravitation fluid from the lungs and to aid the blood and lymph circulation.

2. *Carbon dioxide administration.*—In certain conditions of poisoning, e. g., by coal gas, etc., in which respiration has ceased or has been reduced to the gasping stage, the administration of carbon dioxide is indicated to rouse the apneustic (inspiratory) centre to activity. In the light of our present knowledge this seems to be sound therapy. The addition of oxygen to the carbon dioxide remains a question but it seems best to alternate oxygen properly diluted with air or nitrogen, with carbon dioxide. All these procedures should be supplemented by the author's artificial expiration which also may be regarded as artificial circulation to conserve the expiratory centre.

3. *In acidosis* soçalled respiratory stimulants are contraindicated, i. e., they are to be used with great care if at all. Where the apneustic (inspiratory) centre is overworking under the stimulus of increased H ions in the blood it would be disastrous to whip it to greater activity by any stimulant and more especially by carbon dioxide. Indeed the indication in such conditions is to tone down the action of the inspiratory centre by the careful administration of alkali and thereby insure the continuance of its function pending causative treatment of the acidosis. As in all the acute and in many of the chronic infectious diseases the tendency is toward the reduction of the alkaline reserve and the establishment of acidosis the clinician must be on the watch for diminution of the alkaline reserve which will show itself early by the induction of prolonged expiratory phase.

4. *In increased intracranial pressure* as the result of mechanical, toxic or toxic infective trauma, neoplasms and other conditions, prolonged active expiration should put the clinician on his guard as to the necessity of operative interference. In all such conditions the immediate cause of death is mechanical, due to pressure upon the bulbar centres. Compare Byrne (4). After serious injury of the skull all the signs of increased intracranial pressure should be studied from hour to hour and especially the disturbances of the external respiratory mechanism. In my experimental work I found that with a graded increase of intracranial pressure the respiratory mechanism responded many hours before there was any material change in the pulse rate, blood pressure, or eye grounds. I also found that sudden encroachment of small extent upon the intracranial space was sufficient to induce respiratory disturbances, the first to appear being prolonged, forced expiratory phase.

However, not every slight disturbance of the respiratory mechanism is a positive indication for immediate operation (decompression) for after skull injuries certain mild pressure effects resulting from the edema of repair incidental to mild cerebral contusions (lacerations) and appearing on the second or third day tend to clear up on expectant treatment in a few days. Progressive impairment of respiratory function is, however, in all such cases a distinct indication for immediate surgical interference of the conservative type. The comparatively harmless decompressive operation in all such cases involves far less risk than waiting.

CONCLUSION

In conclusion, it is to be hoped that the clinician will quickly recognize the importance of analytical

study of the respiration as an aid not only to mechanistic diagnosis but also to rational therapy.

Some Remarks on Insect Bites as a Cause of Heart Disease

G. ARBOUR STEPHENS, M.D.,

Swansea, Wales

In this article I desire to draw attention to the following sixteen points:

1. The history of medicine suggests a spasmodic development of heart disease as a pathological entity.
2. Criticism oftentimes is carping and not instructive.
3. The introduction of the stethoscope was a big step in advance.
4. The dangers of dogmatism, as examplified in Watson's theory of the heart sounds.
5. The necessity of knowing the cause of the normal sounds.
6. The cooperation of the general practitioner an absolute necessity in a proper investigation into the cause of heart disease.
7. Historical reference—milk as an important food.
8. The value of milk as a lime bearing food.
9. The amount of milk consumed by children of the poor is practically *nil.*
10. The feeding habits of the poor are bad and made worse by drinking vinegar as well as alcohol.
11. The children of the poor constitute what I call the "acid" class.
12. All rheumatic fever and chorea cases occur among those of the "acid" class.
13. A deprivation of lime bearing food and a further depletion of lime by vinegar drinking result in an unstable mechanism.
14. This instability constitutes a predisposition toward carditis as a part of the attack of rheumatic fever or chorea.
15. Such an instability tends itself to a condition of anaphylaxis.
16. This anaphylactic condition is determined by the bites of insects.

Harvey described the circulation of the blood and the use of the heart in 1628, and ten years later Walaeus, professor of medicine at the University of Leyden, demonstrated what is now known as the sinoauricular node as well as the phenomenon at present described as fibrillation. Notwithstanding the large amount of experimental work done in connection with the circulatory system of animals, as well as man, during the twenty-five years following Harvey's great discovery, when transfusion was undertaken, and drugs of all sorts injected into the veins for the treatment of disease, heart disease was not considered as a pathological entity until about two hundred years later.

The introduction of the stethoscope in 1822 as a useful aid to diagnosis seems to have given a new impetus to the investigation of disease, with the result that we find Watson, in his lectures discussing volubly on the connection between acute rheumatism and heart disease.

Historically one might perhaps modify the statement regarding the recognition of heart disease as an entity, for we find that 1000 to 2000 years B. C. there was written in the Bible (Proverbs 14-20), "A sound heart is the life of the flesh," while the association of faintness with a cardiac disturbance was very general. Throughout the pages of Holy Writ there seems to have been a general agreement as to the most suitable treatment, namely, "wine that maketh glad the heart of man," and although no worse than most of the drugs used for heart trouble is, prohibition notwithstanding, certainly the most palatable.

Although such excellent work was done in the interval between Harvey's discovery and the foundation thirty years later of the Royal Society, unanimity was not general among scientists at that time, nor was criticism of the impartial and impersonal nature one ought to expect from learned men.

In the Medical Journal and Record for November 21, 1923, I quoted from the *Epistles of Walaeus,* wherein he stated that, "No man can publish in Print which some account excellent, but he presently meets with a Detractor who will cut and tear him most cruelly. Now, for a man to seek nothing else by his Cares and labours but Envie and Vexation of Mind, is extreme madness." This hypercritical atmosphere may help to explain why so little progress in medical science followed such great medical discoveries.

That the introduction of the stethoscope had a marked effect on the science of medicine is evidenced by what Watson tells us in his lectures about a case which he saw in 1824. "There had been symptoms," he states, "which indicated the cardiac disease, but at that time I did not know how frequently carditis was combined with acute rheumatism. Auscultation had not yet come into fashion in this country; at any rate I knew little or nothing of its use and I

had supposed that the chest symptoms resulted from rheumatism of the intercostal muscles." However, when Watson fully realized the advantage of using the stethoscope, he went thoroughly to work and laid the foundation of our modern cardiology, but it is interesting to observe how men of dogmatic personalities as well as being great discoverers themselves seem to hold up progress after their day for prolonged periods.

Watson appeared about two hundred years after Harvey, and then we get another period of about eighty years before Mackenzie sets the ball of progress rolling once again. The dogmatic element in Watson was the means of perpetuating the legend with regard to the causation of the heart sounds. He was the first to discuss the sounds of the heart, both normal and abnormal, and he did it with a minuteness which presupposed that all medical men were adepts at analyzing sounds, but a careful consideration of his statement shows a fallacy in what he says.

With regard to the cause of the first sound, he tells us that it "chiefly results from the muscular contraction of the ventricles," and adds, "You are aware that the vigorous contraction of a large muscle is accompanied by *audible* sound." The effect of that fallacious statement is as great today as it was in Watson's time, and is responsible for much misconception, with all the disastrous effects of a false doctrine. Did every large muscle produce "audible sounds"—as if sounds were ever inaudible!—we would, each of us, on the least exertion, be nothing else than a musical box.

For eighty years the medical profession has toyed with this extraordinary fallacy, and we are again faced with a period when the resuscitation by Mackenzie of Waleus's discovery of fibrillation is likely to lead to all the extravagant notions associated with the electrocardiograph, the great excuse for which is that civilization seems to move in jerks which have to be recorded somehow or other. The seriousness of the whole matter lies in the fact that if medical men are misled as to the cause of the normal sounds, their ideas with regard to the abnormal sounds of the heart must be equally misleading.

"Prove all things," the Apostle Paul tells us, "Hold fast to that which is good," and such advice is essentially useful when we are considering electrocardiograms. The mechanically recorded movements of the muscles of the heart, which we call "electrocardiograms," are often published with the *sounds* of the heart depicted on them as well. Such a depiction is calculated to mislead the majority of medical students who accept the opinions of their teachers on sound, as if they were absolutely valid opinions, and as definitely recordable as the movements themselves. This recording of the sounds tends to perpetuate the idea that they are caused by the muscle movements, but if the doctrine is not well founded and correct, it is both wrong and unscientific to persist in such a method.

The extraordinary elaborateness of the electrocardiographic methods lend themselves to wholesale deception both of the instrumentalists themselves and the rank and file of the profession, especially at present when they help to extract good fees from the pockets of the public. The experiments in the period succeeding Harvey's time were elaborate in the extreme, and in many cases even fantastic, but how many of them are ever dreamed of today?

What, therefore, shall we prophesy with regard to the marvelously elaborate therapeutic and diagnostic performances of the present day?

For such reasons let us try and get back to simple things; let us bring our common sense to bear on the common things of our everyday life, rather than allow ourselves to be led into mazes from which it takes at least a generation to extract ourselves. Could we but have the benefit of the wonderful experience of the general practitioner put before us in a suitable manner, what marvelous studies could be elaborated, but failing that, could we but get the general practitioner sufficiently interested in a definite investigation in order to bring his trained common sense to bear on the problem, what wonderful progress would be recorded?

The subject that I am dealing with is one that ought to appeal to all medical practitioners who have the wellbeing of the community at heart, because if anything can be done to stop the increasingly disastrous results of heart disease, it should be done at once.

The great and good work of the New York Heart Association is evidence of the seriousness of the problem from a national point of view, and although considerable progress has been made by way of relief, nothing definite seems to have been put forward whereby the disease can be prevented.

In order to prevent disease of the heart, we must first of all be certain as to its cause, but although we know it is practically part of what we call acute rheumatism, as well as chorea, and is often associated with adenoids and tonsillar trouble, nevertheless the actual *causa causans* still seems to evade us.

Any suggestion which can offer any hope of solving the present puzzle within the limits of common sense is, I venture to think, worthy of every consideration, and under such conditions I put forward my theory of the causation of heart disease. Causation has to be considered from the point of view of *predisposition* as well as *determination*, and taking predisposition first of all, it is important for us to decide whether we can isolate any special class of the community as being particularly prone to heart disease.

All mankind can be divided into two classes, first, those who drink milk, and second, those who do not or cannot do so. The value of milk as a food has been recognized throughout the ages and we are told in the Bible that Abraham could not place anything more acceptable than butter and milk before his angelic visitors. Solomon also states that as a result of diligence, "Thou shalt have goat's milk enough for thy food and for the food of thy household, and for the maintenance of thy maidens." Was not the Promised Land depicted as one ever flowing with milk and honey? Alas! how far are we in England from that land of promise when the average amount of milk sold amounts to less than a quarter of a pint a day for each person. One evidently has to go west to reach the promised land, if milk is any criterion, for in the United States the amount consumed daily works out at a pint a head. In Oriental lands one is struck by the universality of milk drinking

among the very poorest, and everywhere one sees a goat; one is also surprised at the absence of rheumatic fever and its sequel, heart disease.

Among the poor in England, and by that one means those who by virtue of their low wages are on the poverty line, the amount of milk consumed is quite a negligible quantity. Such wages do not allow of the members of these families having more than two ounces a head at most, but if the father spends any money on alcoholic drink the quantity of milk consumed in the family is reduced to nothing. Small as is the quantity for each person as worked out by statistics, in practice we find that of children in these poor homes, thousands receive no milk at all, while many or most of those who do get a little, get it in a very poor and dirty condition. How nations can hope that A1 men and women will be reared under such conditions passes all comprehension, while to allow a continuance of the conditions which breed persons of the C3 type is a fearful reflection on those in authority. "Ask and ye shall receive," is the advice given in the Scriptures, but if the people know not for what to ask, how can they possibly be expected to obtain the essentials for their wellbeing.

The demands of the populace at times of parliamentary and municipal elections are merely those they have been taught by their socalled leaders to repeat in a parrotlike fashion, and our hope for better things is to have leaders of high principle who will instill into them the idea of asking for the essentials of clean living and wholesome lives. At the present moment we are faced with the fearful fact that thousands of our fellow creatures do not get any of that most valuable of foods—the lime bearing milk.

To be deprived of this important food is bad enough, but when we find that many of the class who drink no milk aggravate matters still further by depleting their systems of the calcium salts by drinking acids, such as vinegar, sauces, lemons, oranges, the case is hopeless, because in this subclass of what I call "acid" children some serious disease, especially rheumatic fever and chorea, will develop in all or practically all.

The great value of milk lies in the fact that it is a great lime bearing food, the ash of milk containing as much as twenty-five per cent. of lime salts; in the ash of eggs the percentage is still higher, while in that of meat it is two per cent. or less. Lime can be said to be of the essence of life, because without it we could not exist or even develop into forms worthy of existence. When comparing a pharmacopœia of thirty-five years ago with one of today, no more striking change is noted than that under the heading of calcium, and it was while I was a student of Sidney Ringer at the University College Hospital, London, that I realized the great value of the lime salts. Ringer at that time was busy conducting experiments to show that lime salts were essential for the development of the ovum, as well as for the beating of the frog's heart. The experiments showing the necessity of keeping the frog's heart bathed with a solution of lime salts so that it might continue contracting are all the more interesting today when we know of the immense value of lime salts in connection with disease of the heart.

Digitalis and other drugs give more dramatic results no doubt, but taking all heart cases into account, one can do greater and better work by prescribing calcium intelligently. Heart work is certainly coming into its own, but unfortunately there are crowds of practitioners who still think that a murmur means either digitalis or a death certificate.

Not only is it necessary for the muscular fibres of the heart to be supplied properly with lime salts, but the circulatory blood must also have its proper percentage. The close association between the blood and the bones, especially with regard to the origin of the former, is of importance when we remember that the analysis of healthy bone shows that calcium salts form fifty-seven per cent. of the whole structure.

In rickets the lime percentage of bones amounts to only twenty-six per cent. and one can easily realize that the metabolic end products in a rickety child with a reduced lime content are quite different from those of a healthy child, while it requires no great amount of imagination to understand why the injection of say antitoxin gives rise to a considerable circulatory disturbance, such as urticaria. The accidental injection of a toxin of disease must also result in quite a different reaction when it takes place in a lime depleted rickety child, from that which takes place in one with normal calicum metabolism.

Chronic ulcers of the leg occur among the poor in whose diet the lime containing fluids are conspicuous by their absence. In the *British Medical Journal,* July 11, 1901, I demonstrated the value of calcium iodide in such cases. Such ulcers occur among the poor in India, making these persons conspicuously offensive in the bazaars by their foul smells. It is interesting to note, however, that those natives who can afford it chew Pan or the leaves of the *Piper betle* wrapped around a small amount of lime. Here is evidence of a natural, instinctive effort to make up for the deficiency of lime salts in the food.

In *The Hospital,* February 4, 1911, I drew attention to the deficiency of lime salts in the dietary of soldiers on active service; the drain of lime salts from a body badly supplied with such, is increased by efforts of an exhaustive nature, and when to this draining is added the depletion that follows the drinking of alcohol, it is no wonder disease becomes rife. Even acid drinks, and especially vinegar, must be looked upon with grave suspicion when drunk by an exhausted soldiery on the field, supplying to me the evidence whereby a predisposition to disease and especially heart disease is created.

The well known result of traumatism in an alcoholic subject, namely delirium tremens, emphasizes the fact that the poisoning of the system or its metabolic disturbance is the great predisposing cause of the tremor. It is difficult to say what is the exact chemical result of such a poisoning, but of this we may be certain that the calcium metabolism has been greatly upset, as is evidenced by the fragility of the bones, as well as by the tendency to erythematous and other inflammatory conditions. The association of a lime depleted system with a tendency to erythema is certainly of interest in connection with the problem of heart disease, for is not the gradation from urticaria via tonsillitis and erythema nodosum to rheumatism one which has been universally recognized?

All children with heart disease are those who do not drink milk, and who deplete their systems sti

further by taking acids, such as vinegar and lemon. These children are very prone to urticaria and local inflammatory disturbances, which are clearly associated with a disturbed calcium metabolism. They are also very readily attacked by fleas, midges, and similar insects. These children alone provide the so-called cases of status lymphaticus, whose hearts fail so readily under anesthetics, because in my opinion a condition of precardial urticaria is produced whereby the intrapericardial condition and its contents are seriously disturbed. What I consider to be the most important element in the condition which predisposes the child to heart disease is, then, a system depleted of lime salts whereby a tendency to local inflammatory conditions is set up; and all these cases occur among those children which I call acid, because of their great partiality for acid and sour things, which cannot by any stretch of the imagination be designated as foods.

How are these children to be recognized? What are the clinical signs which characterize this acid class? They have, 1, inflamed, puffy, or bleeding gums; 2, red raw, or cracked tongues; 3, nailbiting habits, and general irritability; 4, marked epigastric reflexes; 5, pallor, but readily produced dermographs; 6, erratic appetite; 7, a tendency to be easily puffed after exercise; 8, diminished energy and interest in affairs; 9, enlarged tonsils and adenoids.

During childhood the calcium metabolism is one of very great importance, for it is in this period that teeth are erupted, and bones are growing and becoming consolidated. For the growth of bones, lime is an absolute necessity, and with a minimum supply of lime to the system, it is evident that oftentimes a point of much precariousness is reached. In all these cases it is interesting to remark that the calcium content of the blood is apparently not much disturbed, and the explanation seems to be due to the fact that the blood is kept up to sample at the expense of the bones, which become denuded of lime salts and therefore very fragile.

Of course a point is reached when the lime content of the blood is disturbed, and a period of irritability sets in, because the lime salts are very necessary for the movements and general activities of the white corpuscles—so necessary for phagocytosis—as well as for the production of the necessary complements. Experimentally Ringer demonstrated the necessity of a calcium salt solution for the movements of the muscular fibres of the frog's heart, and for the life and movement of cells generally, so that a diminution of the blood calcium must modify the movements of the heart's action as well as the endothelial activity.

Calcium salts have a marked action on the surface tension, as shown when a globule of mercury is washed with a lime solution and allowed to roll on a flat surface. It no longer possesses the characteristics usually associated with quicksilver, but remains an inert mass, ready to assume any shape.

What effect, one asks, has the variation in the blood calcium on the surface tension of the blood cells? Does this affect the diapedesis of the white corpuscles, or the pseudopodic movements of the endothelial cells? If so, is predisposition closely associated with a disturbed diapedesis? Accepting this as a fairly true and accurate statement with regard to the conditions associated with a predisposition towards carditis, it remains for us to try and point out further what is the factor which determines the oncoming of the disease in those so predisposed. Is any toxin introduced into the system? And if so, how and in what form? Is there any protein sensitization associated with some form of anaphylaxis?

Let us consider some of the signs and symptoms associated with anaphylaxis, and we find urticaria, malaise, vomiting, vascular hypotension, a feverish condition, and joint pains or even swellings. Such symptoms are similar to those one finds in acute rheumatism, and the similarity is suggestive. Anaphylaxis is especially prone to occur in those I have designated acid children, possessing a low calcium content.

Dale has pointed out that one of the chief features of anaphylaxis is a poisoning of the endothelial cells, and the determining factor is one which affects the endothelium in different parts, e. g., cold determines a disturbance of the endothelium in the extremities in chilblains. Dale is of the opinion that sensitization is cellular and not humoral in location. The antigen and antibody do not meet in the blood stream, but as the antibody is in a cell, the reaction with the antigen takes place at that spot, whither the complement is conveyed by the leucocytes.

In this connection some experiments of Walker and Holmes are very interesting, in showing a selective response on the part of the leucocytes to the injection of various substances, e. g., glandular substance stimulated the mononuclear corpuscles, and diphtheria the polymorphonuclear ones.

The majority of cases of acute rheumatism occur in the late autumn just after a period when most people have been worried and bitten by insects, such as midges, harvest bugs, and sand fleas, and some of us react far more intensely than do the more fortunate members of the community. In most cases the effects of such bites pass off fairly quickly, but much depends on the dose, which, if big, may produce even in a strong healthy individual some very disturbing general effects.

The effects of insect bites vary from a mere temporary irritation to all the inconveniences which constitute the symptoms of sandfly fever, with its headache, fever, and pains in loins and limbs; temperature raised, the pharynx and tonsils inflamed, while vomiting, epistaxis and gastric disturbances may occur. The cuticular effects are minute red spots, large papular infiltrations, or erythematous blotches, the whole being suggestive of an attack of rheumatism with all the predisposition due to a deficiency of the calcium content. With a definite predisposition, one can understand how the protein may have a specially selective effect on, say, the endothelium of the cardiac bloodvessels, with consequently severe metabolic disturbance of both myocardium and endocardium.

As I said above, injecting a toxin into a rickety child with a very depleted calcium content produces metabolic results and products quite different from those in a healthy child, and the metabolism of the rickety child is so constituted that it is very readily disturbed. All reactions of the body are what I call time reactions, and disease caused by proteins or toxins is, as in catalysis, merely a modification or

increase of the reaction and never the setting up of a new kind of reaction. The introduction of a catalytic agent in the form of a protein toxin by means of an insect bite is sufficient to account for all the change of the time reaction rate in the body of the person bitten, and if the histories of all carditis cases tend to corroborate such a statement, we have every reason to be satisfied with the theory advanced.

What I am particularly anxious for is that medical practitioners throughout the country should test the accuracy of the theory, first of all as to the tendency of acid children and they alone, to manifest metabolic disturbances which we call acute rheumatism, and secondly, as to whether all those children previous to such a development have been the victims of insect bites, e. g., fleas, midges, harvest bugs and sand fleas.

With regard to fleas, as far as I can find out, there is a seasonal or periodical variation in their viciousness, and they bite more readily and with more deadly effect at some times of the year than others. Much has been written on the family tendency toward acute rheumatism and, merely looked at from the similar or equal exposure to insect bites that occur to members of the same family, one feels that there is some truth in the suggestion, but when we remember the familial habits of feeding, i. e., those handed down from mother to daughter, together with an insufficient income, it is easy to realize that such feeding habits are very far from what they ought to be. The children of the poor never get any fresh milk, or only just enough from a dirty supply to discolor their tea, whereas eggs never can at their present price form part of the dietary.

Lime bearing foods therefore cannot form a proper proportion of their food dietary, while their poverty condemns them to conditions which necessitate living in poor houses under dirty conditions, where vermin thrive unrestrictedly, and by their bites produce an anaphylactic condition which results in acute rheumatism together with carditis.

The Large Intestine and Vagus Sympathetic Action by Atropine and Eserine

S. D. LUDLUM, M.D.
and ELLICE McDONALD, M.D., F.A.C.S.
Philadelphia

In our studies of the mechanism of disease, we have correlated the relation of the vagus sympathetic balance of the vegetative (sympathetic or autonomic) nervous system with the hydrogen ion concentration of the blood (p.H.) and their relation to disease processes. We found that the smooth (or nonstriated) muscle of the gastrointestinal tract could be taken as an indicator of the vagus sympathetic balance and that this balance and the smooth muscle reaction could be correlated to the acid base balance of the blood as shown by the p.H. of the blood. We showed this relation in a schema (Fig. 1) which shows better than any description the result of our researches. We produced x ray pictures which showed that the amplitude and postural tone of the large intestine could be correlated with the hydrogen ion concentration of the blood (p.H.), and we demonstrated these results of our observations and experiments.

In this study, inasmuch as it depended to a considerable extent upon the action of the smooth muscle of the intestine as an expression of nerve action, and of the balance of the vagus and sympathetic parts of the vegetative nervous system, it was of importance to meet two possible criticisms: 1, that the postural tone of the intestine (particularly the large intestine) and the arrangement of its haustra really depended upon nerve action and not upon muscular reaction; 2, that the pictures and arrangement of the intestinal musculature was not the result of mechanical accumulations of the intestinal contents, the socalled filling effects, of the radiologists.

For this reason we experimented with atropine sulphate and eserine sulphate. As is well known, atropine paralyzes the vagus and eserine paralyzes the sympathetic branch of the vegetative nervous system. The vagus inhibits the heart and stimulates the gastrointestinal and the pupillary smooth muscle, while the sympathetic stimulates the heart and inhibits the smooth muscle of the pupil and of the gastrointestinal tract. It is obvious, therefore, if we got effects through the hypodermic injections of atropine and eserine, these effects must of necessity be nerve effects and, if the postural tone and arrangement of the large

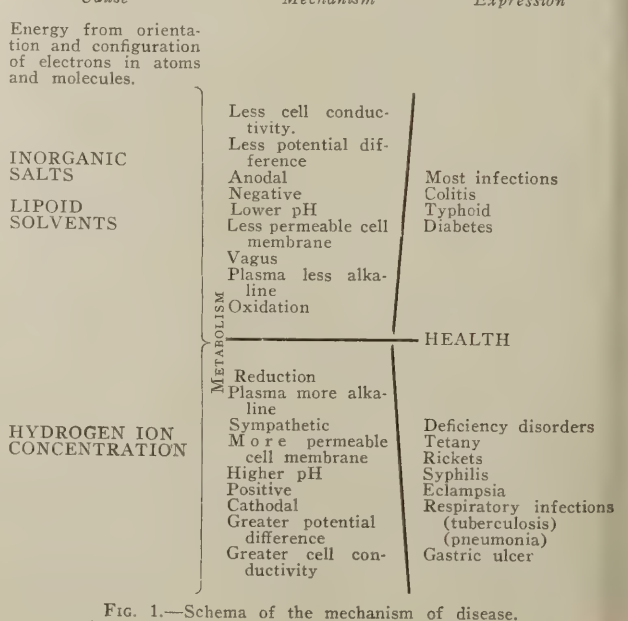

Fig. 1.—Schema of the mechanism of disease.

intestine was altered without alteration in the amount or progress of the intestinal contents, the change in the arrangement of the haustra must essentially be due to nerve action and to the vagus sympathetic balance of the vegetative nervous system. The socalled filling effect is an expression used to indicate a phenomenon inexplicable to the radiologist, but these socalled filling effects are apparently nerve effects. Something makes the intestine take the shapes arrangement and special postural tone that it does (in distinction to the geographic or spatial arrangement) and it must essentially be nerve action as in the action of smooth muscle elsewhere in the body.

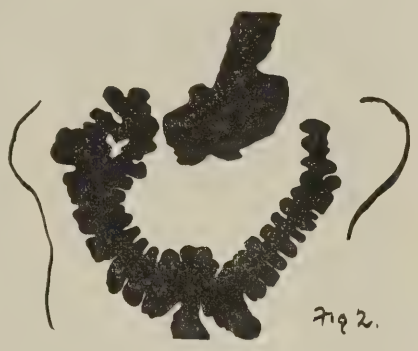

Fig. 2.—First condition of colon and stomach of first patient before atropine.

Fig. 3.—Second condition of colon and stomach of first patient after hypodermic injection of atropine sulphate, gr. 1/75, showing enlargement and obliteration of the haustra.

In our studies of the smooth muscle of the gastrointestinal tract and its relation to the vagus sympathetic balance, the patients were observed under uniform conditions with a uniform barium sulphate meal, and at a uniform time and in the absence of drugs or purgatives. The patient in the atropine experiment was a nurse, with a reasonably normal vagus sympathetic balance, and the patient in the eserine experiment was one whose balance had been almost constantly upon the sympathetic side as was shown by her p.H. which was always upon the alkaline side of p.H. 7.4 and her previous x ray pictures of which we had made a considerable number in a study of her extending over two years. These illustrations are chosen from a number of similar experiments with these drugs. The illustrations were made from direct tracings of the x ray films over the viewing box and the x ray films were taken from the front of the patient. The hydrogen ion concentration estimations were made after the Hawkins's method as modified by Hastings and Sendroy, Jr. (2 and 3).

In the atropine experiment, an x ray record (Fig. 2) was taken of the patient who was then given atropine sulphate, one seventy-fifth gr., hypodermically, and another x ray (Fig. 3) picture was taken forty-five minutes later. The haustra of the colon was then flattened and obliterated and the amplitude of the colon was greater. The stomach had become relaxed. In other words, the vagus action of contraction or constriction had become diminished and the sympathetic action of dilatation had become increased. The action of atropine upon the pupil is well known, and a similar action upon the nervous mechanism controlling the smooth muscle of the intestine is here shown. This effect is translated by us as a sympathetic effect and it is in consonance with the action of atropine in decreasing gastric acidity.

In the eserine experiment, the patient had a dilated intestine (Fig. 4), a sympathetic preponderant state with a p.H. upon the alkaline side from blood p.H. 7.45 to p.H. 7.6. She was put upon eserine sulphate, one sixty-fourth gr., twice daily for six days and an x ray picture of her colon then taken (Fig. 5). Her colon was then seen to be markedly contracted and her blood p.H. 7.35. Here then was a marked change from the sympathetic effect (Fig. 4), with a dilated colon and obliteration and blockiness of the haustra, to a contracted colon with marked vagus preponderance. We have not as yet made enough observations to say that the hydrogen ion concentration of the blood p.H. is constantly changed under vagus stimulation of eserine, but the appearance of the large intestine (Fig. 5) is one we associate with a blood p.H. of this degree. A single hypodermic of atropine will not, in our experience, perceptibly alter the p.H. of the blood.

Fig. 4

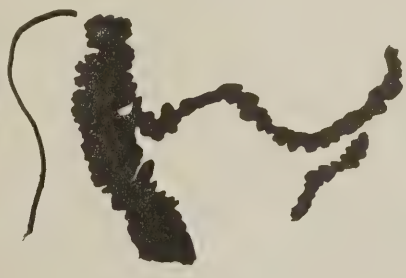

Fig. 5

Fig. 4.—First condition of colon of second patient who was always upon the sympathetic side.

Fig. 5.—Second condition of colon of second patient after eserine showing contraction of the large intestine and a vagus condition with a p.H 7.3.

The conclusion from these experiments is that the amplitude and postural tone of the large intestine may be changed through the vagus sympathetic nerve action by chemical substances, such as atropine and eserine, and that postural tone of the gastrointestinal tract is dependent upon the vagus sympathetic balance of the vegetative nervous system.

The Toothbrush

OLIVER T. OSBORNE, M.A., M.D., F.A.C.P.
New Haven, Conn.

In the hygienic aim of causing the preservation of the teeth by cleaning them with the toothbrush the fact that a toothbrush could frequently become contaminated, therefore a source for perpetuation of an infection which the person may have, and also that it might cause a reinfection, has been overlooked.

It is almost sacrilegious to dethrone the toothbrush from the pedestal upon which it has been placed, but because it has been idealized is no reason why its powers for bad as well as for good should not be studied.

Only very rarely have articles appeared in medical or dental literature condemning the toothbrush. A few of these writings are as follows: Observations on the Bacteriology of Toothbrushes, by H. Smale and D. W. Carmalt-Jones (1); The Sepsis of the Toothbrush, by W. P. Harrison (2), who said, "Not only the public but even dentists themselves have little conception of the filthy state of the apparently clean toothbrush as used in every day life"; an editorial in the New York Medical Journal (3), November, 1919, says, "The implement (toothbrush) was never used so much as it is at the present time, and yet the teeth of mankind were never so bad"; The Toothbrush as a Cause of Repeated Infections of the Mouth, by C. M. Cobb (4), who, after discussing the brush and reinfections, says, "The happy solution of the problem would be for someone to invent a brush which would hold a piece of cotton or felt which could be thrown away after it was once used"; J. L. Kelly (5) says, "The toothbrush is a relic of the dark ages"; C. H. Witthaus (6) quotes Dentz, dean of the dental department of the University of Utrecht, as declaring twenty-five years ago that "pyorrhea alveolaris is generally only the consequence of tooth brushing," and Witthaus in his article says he is converted to the opinion that "the toothbrush is the causal factor in alveolar pyorrhea."

I recently discussed this subject in the New Haven, Conn., *Department of Health Bulletin* (7), and said, "With the evolution of more and more sanitary precautions for the prevention of infection and reinfection the menace of an infected toothbrush now presents itself for consideration. In mouth and throat infections, including diphtheria, tonsillitis, scarlet fever, measles, etc., the toothbrush used just before the patient became ill must be destroyed. It is a menace, and may cause the patient to become a carrier of the disease with which he was affected.

"With tender, bleeding gums the toothbrush is an implement of injury, and the bristles may prick the gums and cause the very infected areas that it is supposed to prevent. The toothbrush is not the proper implement for massage of the gums."

An editorial in this *Bulletin* (7) says, "Is it not about time for those of an inventive turn of mind to put their attention to the development of an instrument that can be used for the care of the teeth that will always be clean and have no element of possible harm to the tender mucous membrane!"

Dr. William Rice, dean of Tufts College Dental School, writing in the very recent book of Dr. C. E. Turner entitled *Personal and Community Health* (8), says that "as a result of experiments" he "has found that a brush rinsed in water after using and then placed in a closed receptacle developed many more bacteria than one which was rinsed in hot water and left in the air to dry."

The dental hygiene instruction now given in many of the public schools of the country consists in part of the methods advocated by Dr. Fones, of Bridgeport, Conn. The term generally applied to the practical part of this teaching is "The toothbrush drill." Generally the drill consists of the children being requested to bring their toothbrushes to school, where class instruction is given by a teacher or dental nurse. Each child puts his toothbrush into his mouth and goes through the various motions of brushing his teeth as demonstrated by the instructor. In the larger schools, at least, the brushes are not washed but are put into envelopes to be taken home and there washed.

It is hardly necessary to prove that from ten to twenty per cent. of all children taking part in this drill have colds, sore throats, infected tonsils, decayed teeth, or sore mouths. Therefore a certain percentage of these brushes must become infected. Food particles removed from the teeth and adhering to the bristles must offer pabulum for the growth of some bacteria, and it is a fact that any used toothbrush can be proved in the laboratory to harbor bacteria, most of which are harmless, but quite frequently pathological germs are found.

Aside from the personal menace of using an infected brush, even if one were immune to his own germs, there is the constant possibility in families of several children (where the toothbrushes often repose in some receptacle in close contact with each other) of others acquiring an infection from these contacts. From an esthetic point of view the toothbrush reposing in a bathroom, where most brushes spend their leisure, is not appealing.

It would seem that after treating a patient who has pyorrhea or Vincent's infection a dentist must caution against the use of the infected toothbrush which is waiting at home to undo the benefit from the "prophylactic treatment." Also a toothbrush used by a person in the incipient stage of an infection should be destroyed or be positively sterilized before it is used during convalescence and after recovery.

City Enforcement of Drug Laws*

S. DANA HUBBARD, M.D.

New York

Federal statistics show that annually in this country some 460,000 men over twenty years of age die from chronic disease. When it is appreciated that for each death reported there are approximately ten cases of such sickness, we find a lush field for the sale of the socalled patent medicines. In plain mathematics, we have annually over four and a half millions of cases of sickness, in all of which the patients are seeking restoration to health in one way or another.

We cannot condemn all of these preparations, but no less an authority than the National Society for the Control of Cancer has declared on this subject as follows: "All proprietary 'cures' are not only worthless in themselves but fatal in that they keep the patient from submitting to surgery until it is too late."

If this broad statement can be true in regard to this malady, may it not with equal positiveness be applied to other conditions?

An obligation rests upon physicians, public officials, and all who deal with happenings to the ill, to stick to the essentials of truth, and if they do so imposition, fraud, and rascality will be relegated to its proper position—which is before the bar of justice. A general conception of the golden rule in this matter, consideration of the ill, makes you your brother's keeper. There is no other way to combat a common enemy. It is this fact which makes this matter of especial concern to all groups of citizens.

THE WIDESPREAD USE OF THE PROPRIETARY REMEDY

In 1888 a gentleman representing a large drug house, doing an enormous business in proprietaries, stated that his firm handled less than a thousand of these remedies. In 1924 this same firm had no less than sixty thousand different accounts of this character.

Many informed persons (professional and public officials) are seriously concerned about these proprietary remedies—but charitably let us suspend judgment until we can gather information of a positive character about this business. How much is due to fraudulent advertising? How much is due to misinformation? How much is incident to stygian ignorance? For it is by knowing facts that we shall be able to wage a successful war against exploitation. In our consideration of the regulation of the distribution of drugs, we have one idea in mind, not to interfere with any honest business prerogative but to make the handling of these agents as safe for the public as it is possible. In other words through supervision we desire to prevent injury or precocious death.

A SPECIAL GROUP FOR CONSIDERATION HERE

Hypnotics.—In the common everyday misuse or abuse of drugs for selfmedication we have found no class of drugs more often abused than those used to produce sleep.

They are all exceedingly dangerous, and the danger is not generally appreciated. Persons who burn the candle at both ends, who work by day and play by night, or who rob the night of its sleep for one reason or another, formerly caught up on sleep through the rather free use of chloral but the use of "knock out" drops by the criminally inclined put this agent in the proscribed class. If there is a market there is a supply, and it did not take the chemists long to synthesize a substitute.

The barbituric acid derivatives today are crowding the market and they are a group which require very careful consideration. Here we find veronal, sulphonal, trional, medinal, and luminal. Of these perhaps the one most sinned against is veronal and this one we have proceeded against by a special act. Formerly when in need of a sedative or sleep producer, it was a simple thing to take a small dose of chloral and go comfortably to sleep. It has often happened, however, that a person, apparently in the best of health, has retired to bed and during sleep has "passed on." We ask ourselves, how many of these sudden deaths are natural? It is somewhat disconcerting to find that in many of these cases the connection between death and a selfadministered sleeping potion was quite frequent.

It is amazing to learn from some of our busy pharmacies—especially those catering to social night owls—how many boys and girls, young men and women on the threshold of a career, resort to hypnotics to obtain sleep.

Investigation also shows that the distribution of these drugs was by a rather limited number of shops in certain localities. It is also disturbing to read the advertisements of some of our department stores, which have drug and cosmetic departments, and learn that these are catering to this trade. Industrial inquiry shows that many young business workers, especially females, are taking up this practice with great frequency.

We have sufficient evidence against these drugs to warrant sanitary code regulations and since we have interdicted this promiscuous distribution it has had a wholesome effect upon their being used for selfmedication in our locality.

COSMETICS

These preparations do not come under the proscription of the pure food and drug act, and so these proprietary preparations enjoy privileges which are many times actually unsafe. Sufficient emphasis has not been placed on the components of cosmetics and the dermatoses which many of them provoke. Many socalled eczemas of women and young girls, if carefully investigated, will be found to be cases of dermatitis venenata, or artificially created inflammation of the skin. The anilin dye used in bizarre facial decalcomania is known to be a positive and dangerous

*Paper read before Association of Food and Drug Officials of the United States at Denver, Colorado, July 30, 1925.

chemical. Paraphenylendiamin, a chemical poison, is a frequent constituent of various hair dyes. Carbolic acid is often used to remove wrinkles. Ammoniated mercury and bichloride of mercury are often used in cosmetic preparations and no more virulent poisons exist, yet their sale is unregulated. Legislation is needed to prohibit the use of anilin dye in cosmetic preparations, of paraphenylendiamin in hair dyes, and mercury in freckle and wrinkle removers. Lead is a known poison, yet it is often added to give body and holding properties to face powder. Bismuth is found in many socalled liquid powders. Here we also find anilin used when it is desired to make a bizarre tint. Pumpkin colored powder has been known to cause inflammation of the cheek quite often, in fact, in some quarters this is so apparent that we find women of the stage cautioning their sisters of the dance hall about its dangers. The lip stick has already claimed in death some of its votaries. We find these highly colored affairs are tinted with anilin. In general it may be safe to assert that all dyes of a chemical nature do some damage to the hair and skin. This is especially a menace when anilin is used in any manner.

It may seem out of place to discuss here the esthetic side of this problem but we are reliably informed that in this country there are annually used some 240,000,000 packages of rouge, which in the main is harmless but the element of danger in the balance of these preparations, especially those using anilin, is considerable. In our experience with hair dyes, and we have tested some eighteen different preparations in our laboratory, we found paraphenylendiamin in every one of them, and some nine of these firms have been brought to court, but owing to the difficulty of legally connecting cause and effect we have not been as successful in these cases as we would have liked.

Here then, we would like to recommend that cosmetics containing chemicals of any character be included in the amendment to our pure food and drug law. We have included many of these in our code—mercury, alcohol, etc.—but we have not been able to go the length thought necessary to make such goods safe and free from hazard. The fact is undeniable that there are many dangerous drugs contained in a great many of the modern beauty preparations, which are being frequently sold as quite harmless and safe preparations.

START OF STUDY OF THIS PROBLEM

My interest in drug regulation is not new. For over thirty years I have devoted a good part of my time to the work and study of this problem. My attention was attracted to this condition very early in my medical career, through having met with a serious and most regrettable accident. A lady, the mother of five little children, was advised by a neighbor to take a certain preparation for headaches, from which the little mother was a chronic sufferer, and on this bad advice, honestly but ignorantly given, this woman lost her life. Rabid and excessive talking, supported by worse than loose newspaper advertising of drugs, has so misinformed the public about therapeutics that many thousands of human lives have been needlessly sacrificed in addition to a useless and needless waste of considerable money.

PROGRESS IN REGULATION

In spite of adverse and foolishly inimical attitude of both the press and business toward progress in the regulation of drug distribution we think that considerable advancement has been made, which while slow, has been steady and certain. The recent move by the advertisers themselves in this matter—the better business advertising group—has been a step in advance, and we expect to see much needed legislation favorably considered and more general public cooperation than heretofore given in this direction.

In the matter of securing legislation, at least in New York, merchants associations and business groups have not been cordially cooperative in these matters. In fact, in nearly every single move we have been opposed by astute legal counsel, publicity propaganda most hostile, and an influential lobby. However, through ability to make our own code, we have been able to devise regulations with the force and effect of public statute, and through these prosecutions have been able to impress favorably, not only the press but a number of influential persons. A death, a damage, or a fraud case, when successfully prosecuted, teaches many admirable lessons. On the other hand, cases lost in court seriously handicap our efforts.

Our legal counsel is most insistent about getting positive evidence that can be proved in court before he will advise the serving of even a summons. In fact, our lawyer informs us that our cases must be almost legally perfect, as we are the initiators of the action. The losing of these cases makes a hostile court, prejudices the jury, and furnishes opportunity for adverse criticism by the press.

Although we have not as yet accomplished all that we hope to do in the matter of drug regulation, we are abundantly satisfied with our past efforts and are encouraged actively and aggressively to extend our activities in these respects. The reaction of business now that the utter sordidness and disregard for human health has been legally proved and the offenders not only exposed but penalized we are reaping the fruits of our hard labor in behalf of the public, but the battle is not won, for there is still considerable to be done.

Today drugs are better prepared, and the methods of standardization have been improved. The people are being taken into confidence and many are becoming interested. The recent discoveries in diabetes treatment by our neighbors to the north of us gave our press and our people considerable light on the methods of modern therapeutics and this public health education will do much to kill the exploiting market. However, there are still a few who are selling dandelion flour as a cure for "sugar secretion." If knowledge is spread intelligently in these matters, not only by scientists but by public officials, we will find consistent with this relationship, distribution will be at least on a par with this progress.

It has been of interest and value to me to attempt to outline many paths along which regulation in our territory should proceed in the future, and here, in passing, let me urge that the regulation of the distribution of drugs should not go any further than the public is willing to accept.

There are many important paths for progress in

this regulation, but which if taken without educating the people for its necessity, would be quickly followed by failure because these efforts would not receive cordial cooperation without preliminary education. If there was a prohibiting statute enacted it would cause a hostile reaction by both press and business.

The constant discovery of new drugs, and new uses for many of our old drugs, makes the problem of public regulation one of considerable importance to a great many people. No two persons react in exactly the same way, in fact in a careful study of those drugs used frequently by laymen for selfadministration—sedatives for instance—we find naturally many abuses. Considerable of this habituation has been checked through our admirable federal statute (the Harrison Law) but this is a limited statute while we have in mind the extension of this prohibition to every drug known as a poison—and accepting this term in its broadest scientific interpretation in this respect. In fact regulation should be extended to all drugs that might in a way be unsafe for the uninformed to handle except in a regulated manner.

We must, in the interest of life and comfort, establish in the future more exact and accurate directions for the use of dangerous drugs.

People in all walks of life and in all kinds of occupations, gather together, for the purpose of discussing problems common to the members of these groups; here they gain knowledge and experience from the experience of others. I cordially endorse and advise conferences.

When a doctor, or an official of our public health service, gives to the public facts regarding the dangers of drugs, the manufacturer, exploiter, or jobber of a "remedy" has on tap a "stock" retort.

Let one advise the public to get vaccinated, to become immunized, to avoid certain places, to do certain things, either to stop an epidemic, to prevent certain diseases, or to prevent accident, just that moment there is a contrary spirit aroused in many to want to do just the opposite.

Emotions play an enormous part in this undertaking, because they form the expressive link between thought and conduct.

The patent medicine man's excuse, when his business is attacked, or hit by regulation, is the age old one of competition. He comes before us and complains about his competitor.

Every lurid misleading advertisement of the scaring kind that frightens the healthy into the belief that they are ill, sends at least four such persons to a doctor to every one that it sends to the advertised remedy.

A concrete case here was pleasingly demonstrated in the sale of a new tooth wash. This firm started out on the pyorrhea problem. They had a good preparation and they had money so to get the public to buy those goods they started to advertise. These advertisements bordered more on the untrue than on the true. They were wholly misleading, dishonest, and their statistics startling. People read these advertisements.

We had them come before us and we directed them to revise their copy or stand a law suit. They revised. I then asked one of the dental societies what was the effect of this advertising on the dentist's business. Of some ten dentists, doing a large practice among high society folks, three of them reported that their practice was considerably increased by patients, heretofore unconcerned about their teeth, anxiously inquiring about the condition of their mouths. One of these gentlemen said he was sorry to see the advertisement modified because it was making good business for him.

No small proportion of the clientele of physicians are those who neglectful of disease in its early stages many times firmly believing the assertions made in advertisements for fraudulent medicines have placed unwarranted confidence in these products until the malady has advanced to a stage where not only medical advice is imperative but where prolonged treatment is essential and often in many of these cases it is too late for more than palliative treatment to be given.

Fraudulent medicine business is a doctor's greatest boon and so far from curtailing the income of the average physician as has been said these secret remedies augment it.

A patent medicine, in the strict legal sense of the term, is a medicine whose composition, or method of making, or both, has been patented. Evidently, therefore, a patent medicine cannot be a secret preparation, since its composition must appear in the patent specifications. Nearly every nostrum, instead of being patented, is given a fanciful name, and that name is registered at Washington, thus becoming for all time the property of the exploiter.

I have time and again described a nostrum as being nothing disguised as some thing. The word remedy, however, in this relationship acquires a sinister sound at which both doctor and druggist shudder on hearing it from the lips of a selfprescriber.

PURPOSES OF PATENT MEDICINE REGISTRATION

Education of the people regarding the dangers of selfmedication. Prevention of the sale of unsuitable remedies. Prevention of substitution. Preventing the sale of habit forming agents under disguise. Preventing of the making of hypochondriacs. Checking misleading and fraudulent claims for a secret operation. Preventing deceptive sale of poisons. Aiding in enforcing such statutes as the Harrison and Volstead laws.

Every locality, in this connection, has its own problems, and in this respect but few are similar. In a large town with many foreigners and transients, we perhaps have problems not met with anywhere else, in fact such is our hope at any rate.

The New York City Board of Health has studied this problem a number of years before any action was taken and when action did begin, it was opposed from the onset by business. Every move was contested in the courts and in nearly every instance the fight was so bitter that no matter which side won, the lower court's opinion was never satisfactory and so up step by step, from magistrate, to Session, to Supreme, then to the Court of Appeals.

The regulation regarding these agents required no less than four years to get a law that would stand the test, and at the same time have sufficient teeth to make such enforcement reasonably satisfactory and not a farce.

The following are the captions of our regulations:

Manufacture and sale regulated,
Definition of adulteration, misbranding,
Prohibiting fraudulent representation,
Sample distribution regulated,
Poison—distribution and sale regulated,
carbolic acid, wood alcohol, mercury,
habit forming drugs, hair dyes,
Toilet preparations sale and distribution regulated,
Condemnation and destruction authorized,
Medicated alcohol sale and distribution regulated.

Perhaps the brief mentioning of these captions is sufficiently explanatory here but I would like to add a few words about habit forming drugs—prohibited acts constituting a menace. We are, no doubt, alone in our interpretation of this evil but as necessity knows no law so when we face a menace we have the power to meet the situation and in this connection our counsel took a route perhaps technically unconstitutional but expedient. It so far has not been contested and having been in operation now for several years and giving satisfaction in these cases we are rather proud of the pioneer experience.

The following is the statute: "Pestilential disease shall be deemed to include the conditions and symptoms resulting from the habitual use of habit forming drugs, and known as drug addiction."

CONCLUSIONS AND RECOMMENDATIONS

The first move in protecting the public from this evil will be to demand that all concerns selling remedies for self treatment, or used by any healing establishment not on a doctor's order, be required to declare on the label the names and quantities of those ingredients for which therapeutic claims are made. This attest would destroy secrecy, it would hit the crooked patent medicine faker the hardest blow that could be dealt. This is a reason why these persons fight every bill or ordinance or any suggestion looking toward such nonsecrecy.

Second: Any patent medicine containing an appreciable quantity of a scheduled list of dangerous drugs to bear the poison label.

This is done in England but the fault with the British Pharmacopœia is that their list of dangerous drugs is not comprehensive.

Imagine, in this connection, that before legal regulation of these agents, many patent medicine soothing syrups, for use in infants, contained heroic doses of morphine, disguised. No wonder these goods earned for themselves the soubret "baby killers," because they earned the title when they destroyed these tiny lives through such abuse.

Third: Prohibit, for selfmedication, all remedies promiscuously sold, containing drugs declared so dangerous as ordinarily to require a physician's prescription and all drugs for which physicians cannot prescribe without filling out certain blanks that are kept as Federal records. This would at once disbar any patent medicine coming within the Harrison or Volstead acts.

Fourth: Amend the present Federal Pure Food and Drug Act governing the sale of these remedies to cover claims made for such medicines *wherever such might be made*. Not simply "in or about" the package. This would do away with the present anomalous state of affairs, which, while prohibiting the patent medicine maker from making false or fraudulent claims on or in the trade package, which does not come into the hands of the public until after purchase has been made, and which permits him to make false and fraudulent claims in avenues of publicity—newspapers, billboards, circulars, hand bills, through which sales are ordinarily effected.

All cosmetics to be brought within the scope of the pure food and drug act. It is an absurd state of affairs that the national law should limit the definition of drugs only to those preparations that are used for the cure, mitigation, or prevention of disease.

Finally: All drugs or chemicals used for domestic purposes, and which are known as poisons, dangerous drugs, to be plainly marked, to have the usual poison marking, and to have antidote and suggested first aid clearly printed on the package.

I have here a label taken from a can of caustic, used for dissolving vegetable fibre in plumbing, sold promiscuously to any one. The carelessness of this form of distribution is most reprehensible. Sight may be destroyed, skin disfigured, and life itself threatened but not a semblance of the danger is noted on this label.

The only possible argument a manufacturer can offer under these circumstances is that properly to identify these drugs might hurt their sale. Every one must admit that from a public health point of view it is the only rational thing to demand. Safety should be considered before profits.

If these simple and easy recommendations meet with your approval, and you endorse the suggestions, it will be but a short time before your influence will be felt in the halls of our legislatures and these protections then will be given to the people. These regulations would go a long way in curbing the evils of the patent medicine industry.

In closing, might we not ask, if proprietorship, in common preparations (mixtures as ordinarily sold in this connection) is not wrong? Proprietorship of remedies produces a condition that makes it commercially necessary to make false claims and to fraudulently deceive the public in order to sell his stock to advantage. Is this not economically most unsound, inasmuch as it is against the welfare of the person and contrary to the interests of public health?

Skeletal Traction.—. J. Moorhead (*American Journal of Surgery,* May, 1925) finds that skeletal traction has demonstrated itself as a useful and safe procedure in certain recent fractures, particularly that group in which reduction and maintenance has hitherto demanded open correction with or without the use of nonabsorbable material, such as plates, wires, screws, bands or clamps. Certain fractures of the femur, notably the supracondylar group, are in many cases irreducible except by open operation or skeletal traction; the latter is preferable because safer and simpler. Skeletal traction has wide application in compound fractures because the traction medium can be introduced at a distance from the wound, and further because the necessary dressings can be unhampered inasmuch as splintage is reduced to the minimum. It permits ready inspection of the limb and lends itself to mobilization of the entire musculature and adjacent joints. With osteotomy through the fracture line skeletal traction replaces extensive operations in malunion.

Practical Therapeutics

THE USE OF SODIUM IODIDE INTRAVENOUSLY IN INFECTIONS AND ALLERGIES

JAMES W. WILTSIE, M.D.

Binghamton, N. Y.

We know that infection by pathological organisms stimulates an immunity reaction. If adequate, the organisms are destroyed and the patient recovers; if inadequate, either death or a chronic or subacute condition ensues. The mechanism of the immunity reaction is as follows: the infecting organisms or their excretions, acting as antigens, stimulate the formation of amboceptors to bind them with complement and render them harmless. This is called complement fixation. Leucocytosis accompanies this reaction, probably for the purpose of destroying the end product.

However, another type of immunity reaction may be developed against substances parenterally introduced and normally nontoxic. It is first necessary, however, that the cells whose function it is to elaborate amboceptor be sensitized to these substances. The initial introduction produces no toxic effect. The organism apparently resents them, however, as entrants to the body in an unnatural way, and in two or three weeks is equipped to bind them in complement fixation should they again be introduced. That is, the process of sensitization is complete.

The first type of immunity we will call true immunity, as it is conservative and cannot as a rule be artificially destroyed, although there is a tendency for it to depreciate gradually. The second type of immunity is commonly called allergy or anaphylaxis. It is really a false immunity. It is characterized by an unusual or exaggerated specific susceptibility to substances normally nontoxic. However, it is nonconservative, usually permanent, but can be, at least temporarily, artificially destroyed. This false immunity is the result of a vicarious attempt of nature to protect herself against foreign dead substances entering the body in an unnatural way. Apparently, however, this attempt of nature at protection is more harmful than the presence of the foreign substance itself, for the product of this complement fixation is extremely toxic and the cause of all allergic and anaphylactic symptoms. This reaction is also accompanied by a leucocytosis, probably also for the purpose of destroying the end products of the reaction. The reason for the increased toxicity of the end products of complement fixation in the case of false immunity is not fully known, but might well be due to the elaboration of an imperfect amboceptor, thus permitting the formation of secondary end products of a toxic nature.

It is commonly believed that the introduction of any foreign substance into the blood stream calls forth a leucocytosis. I wish to suggest that it is merely as an accompaniment of complement fixation that this leucocytosis occurs. It is my belief that the foreign substance acts either directly or indirectly as antigen or antigen producer—that a complement fixation occurs and that phagocytosis exists to destroy the end products of complement fixation.

In treating a series of cases with sodium iodide intravenously I have observed what I believe to be the development of a true immunity against the organisms producing the pathological condition for which the treatments were given. In infections I have observed local reactions, general reactions, a marked increase in leucocytosis, recovery of the patient and a tendency to nonrecurrence of the infection. In control cases the leucocytosis is comparatively slight, and local and general reactions do not occur. However, as it is almost impossible to find a perfectly normal person, any slight increase in leucocytosis may be interpreted as a response to complement fixation in some degree, too slight at times for the production of clinical symptoms. All allergies show an existing real or relative leucocytosis, as evidence of the active presence of complement fixation. In these cases the intravenous use of sodium iodide paradoxically reduces the leucocytosis.

Do not misunderstand me. Leucocytosis may and does exist for other purposes than destroying the end products of a complement fixation reaction. However, in intravenous injections of foreign substances I believe *that* to be the action with which we are dealing.

It is by chance alone that sodium iodide was the salt that directed my attention to what I believe to be the real cause of the production of a leucocytosis following the intravenous use of any foreign substance. Yet I believe that it is the salt best adapted for this demonstration. Sodium iodide does not act primarily as an antigen; it is merely an antigen liberator, probably the best we have.

So far as I have been able to determine, sodium iodide has only two primary actions: First, it stimulates all living protoplasm; second, it promotes a lysis and distintegration of all dead and dying protoplasm and all pathological exudates. Perhaps the apparent specificity of the iodine ion in these actions is analogous to its action as an ingredient of thyrotoxin—the body's natural stimulator of metabolism. As a result of the second mentioned primary action of sodium iodide we get a sudden flood of split proteins and released bodies of dead bacteria entering the blood stream. It is these that act as antigen and stimulate amboceptor elaboration. Increased osmotic pressure of the blood and lowered viscosity of the lymph may materially hasten absorption of these broken down proteins.

To illustrate by a typical case.

CASE I.—Mrs. C. entered my office September 17th complaining of chronic soreness and tenderness in the right side. She had suffered from it for years. It was unrelieved by medical treatment. She had had an appendectomy years before, also the removal of a ruptured ectopic pregnancy on the right side. Her local and general symptoms led me to suspect a chronic cholecystitis. However, her symptoms were no worse this day than they had been for a year past. I took a blood count which showed 4,800 leucocytes,

60.5 per cent. polymorphonuclears, 36.5 per cent. lymphocytes, 1.5 per cent. each of large mononuclears and eosinophiles. I then gave her thirty-one grains of sodium iodide intravenously. This was about three o'clock in the afternoon. By six o'clock an acute pain had developed under the ribs on the right side. She ate a very light supper. After supper she vomited. The pain increased and the vomiting continued. I saw her at ten o'clock. She presented a typical picture of gallstone colic. The pain was so severe that she said she felt as though she were breaking in two in the middle. The tenderness was most marked over the region of the gallbladder, and the pain radiated from this region directly through the right side to the scapula. Her pulse was 80 and her temperature 98°. I called in a surgeon and his diagnosis was gallstone colic. Operation was refused that night, so I gave her a hypodermic injection of morphine and went home. Next morning I took a blood count, twenty hours after the first blood count and the injection of the sodium iodide. It showed 10,000 leucocytes, 85.5 per cent. polymorphonuclears, 14 per cent. lymphocytes. Her pulse was 80, temperature 99°. Operation was performed four hours later. A chronically infected gallbladder was removed. No gallstones were found.

The patient made a quick recovery and all pain disappeared. I believe the sodium iodide dissolved exudates and released bacterial proteins, thereby stimulating specific amboceptor elaboration and producing a local reaction. The general reaction was slight, but the leucocytosis was quite marked.

About a year ago I had been treating two cases of chronic pyelitis at intervals for months, by bladder irrigations and urinary antiseptics administered by mouth. In each case I finally tried sodium iodide intravenously. One case cleared up after three injections, the last being given on November 15, 1924. The other required a few more, the last being given on January 26, 1924. There was no recurrence in either case. It seemed as if an immunity had been established.

Case II.—I was called to treat a case of abrasion of the skin of the shin. The patient had treated herself for several days with home remedies. When I saw her the abrasion had become an indolent raw sore about two inches long and one quarter of an inch wide, directly over the tibia. It was inflamed over a radius of half an inch all around, and very tender. I prescribed a wet dressing of a mild antiseptic solution to be changed twice daily. After a week I saw this patient again. If there was any change in the condition of the wound it was not for the better. The base was indolent and ulcerative in appearance. The inflammatory area was dark red and increased in extent. The whole region was extremely sensitive to touch, and painful. I changed the wet dressing to one of aluminum acetate solution and continued for two days more.

My patient was becoming dissatisfied and alarmed, as there was not the slightest improvement. The pain, tenderness and aching were making her hysterical; so in desperation I decided to see if sodium iodide would stimulate healing. I told her I was going to give her something to purify her blood, and then injected thirty-one grains of sodium iodide intravenously. The pain was gone before she left my office. After six hours it gradually returned, and at the end of twenty-four hours it was worse than ever, and she had a temperature of 99.8°. The pain extended to her hip, and she said it felt as though it were boring right through the bone. On the other hand the edema about the wound had disappeared, and it looked healthier. The inflammatory area still persisted but had become pink. The patient said her head felt queer and she wondered if she were going crazy.

I decided to use another iodide injection to relieve the pain and aid in healing, as I felt the first injection had really benefited the local condition. This time I used the combination of sodium iodide and hexamethylenamine. The pain was relieved instantly, and the patient felt better generally, at once, and left the office in a very happy frame of mind. The wet dressings were continued, using boric acid solution and glycerine as at first. Four hours later the pain began to return. At the end of seven hours the whole leg was painful from her foot to her hip. I saw her at once and found her very hysterical, suffering acutely. The wound was oozing blood over its whole extent. The raw area had extended, having broken down whatever new skin formation had already taken place. The inflammatory area had increased to take in a radius of one inch all about the wound. It was more edematous than at any time. I confess I was much alarmed at her condition.

I continued the wet dressing, gave her a sedative and went home. The next day I saw her three times. Each time I felt there was some slight improvement in her general and local condition. Eighteen hours after this acute reaction the wound began to bleed again, so I changed the wet dressing once more to aluminum acetate solution. The following morning the wound appeared much better, the patient was feeling better in every way, and most pleasing of all, the tenderness, pain and aching had entirely disappeared. By that night the wound presented the most healthy appearance of any time up to the present. The inflammatory area was very narrow, and pink. The base of the wound looked healthy, and all edema was gone. From then on the wound healed as any normal wound should. In one week it was closed.

I regret I made no blood counts in this case. The Wassermann reaction was negative. I believe the iodide when first given dissolved the exudates in the neighborhood of the wound, and by suddenly releasing protein antigens into the blood stream provoked the elaboration of amboceptors to bind them in complement fixation. It was a mistake on my part, however, to give sodium iodide a second time in twenty-four hours, as in so doing I did not wait for the negative phase, and consequently produced a severe local and general reaction, analogous in a way to the result I might have expected if I had given a hypodermic injection of a vaccine twenty-four hours after an initial subtoxic injection.

Case III.—J. R. had had a thorough examination by the Life Extension Institute. Two teeth were found by x ray to show areas of rarefication at the apices. They gave him no trouble, but he did not feel his best. His mental processes were slow, he was easily fatigued, every act was an effort. After

receiving an injection of sodium iodide he complained that these two teeth were tender. They were extracted and found to be abscessed. Improvement in general health followed.

Case IV.—W. T. M. entered my office complaining of neuritis in the right shoulder of eight or nine months' duration. One tooth, supporting a bridge, had been very tender for two weeks. X rays showed no apical abscess. However, it was still very tender and showed a condition of pyorrhea. He had felt more exhausted, and tired more easily since this tooth had troubled him. A blood count was taken and showed: white cells 6,000, polymorphonuclears 53 per cent, lymphocytes 42 per cent, eosinophiles 3 per cent. Thirty-one grains of sodium iodide were given intravenously. Next day the tooth was much less tender and the patient felt better generally. The blood count showed 9,000 white cells, 60.5 per cent polymorphonuclears, lymphocytes 33.5 per cent, eosinophiles 5 per cent, and large mononuclears 1 per cent. The following day another injection of sodium iodide was given. The neuritis had practically disappeared after this, and all soreness had disappeared from the teeth. The patient felt stronger, was less exhausted and more like himself. Six days after the first injection another blood count was taken. It showed: white cells 7,000, polymorphonuclears 62.5 per cent, lymphocytes 32 per cent, eosinophiles 3.5 per cent, and large mononuclears 1 per cent. A third injection of sodium iodide was given. Next day a fourth blood count showed: white cells 7,600, polymorphonculears 76.5 per cent, lymphocytes 21 per cent, eosinophiles 1.5 per cent, large mononuclears 1 per cent.

(*To be concluded*)

NONSPECIFIC PROTEIN THERAPY IN PELVIC INFECTIONS

Julius Jarcho, M.D.
New York

In bringing nonspecific protein therapy again to the notice of the medical profession I may perhaps offer an apology for taking up their time with something that is not new. However one may be excused if the seriousness of pelvic infection is considered, the amount of suffering this condition causes to young womanhood, sapping their strength during the best years of their lives and often terminating fatally.

In this country credit must be given, in addition to Petersen, to G. Gellhorn for citing the beneficial results of protein therapy.

This method of treatment has not as yet gained the popularity it deserves and has not been used as extensively here as in many European clinics.

In several of the Central European clinics I have noticed that pelvic infections—whether after gonorrhea, after abortions or postpartum—are combatted by means of various nonspecific remedies such as colloidal iodine, colloidal silver, proteins and, in chronic cases, turpentine preparations.

In many of the Viennese clinics caseosan (a casein preparation) is in use. In Prague at Wagner's clinic cow's milk has been used for injections in a great number of cases. My own cases though limited in number were so uniformly satisfactory under milk treatment that I feel justified in reporting them here.

All my patients except one came under my observation quite early in their illness so that I was able to follow the cases from the very inception of the illness. Most frequently these patients showed signs of pelvic or generalized peritonitis following deliveries or attempts to induce criminal abortion.

In one case an attempt was made by intrauterine injections of drugs to induce abortion in a nonpregnant girl of eighteen years who thought herself gravid. She was taken violently ill with severe abdominal pain and was admitted to the hospital with symptoms of general peritonitis. Because of marked rigidity, extreme tenderness and small introitus, the pelvic examination was unsatisfactory. The temperature was high, the pulse rapid and thready. The usual peritonitis treatment was followed,—Fowler position, icebags, Murphy drip, sedatives and stimulants. When the more acute symptoms disappeared pelvic examination revealed a small conical cervix with pin point os, and a mass which filled out the entire pelvis and reached a few centimetres below the umbilicus. According to the size of the mass which could be taken to be the uterus, the patient appeared three and one half months pregnant. Colloidal iodine and colloidal silver had little influence on the condition of the patient. Then milk was used and the exudate cleared up rapidly leaving a small uterus. The patient was not pregnant; she has since passed through two normal menstrual periods with proper intervals and normal flow.

A second patient, who had a generally contracted pelvis and previous Cæsarean section which left a weak uterine scar, showed a large intramural fibroid. A classical Cæsarean section was performed with myomectomy and sterilization by resection of the interstitial portion of both tubes. After the operation an exudate appeared. It extended from the uterus to the fascia, forming a large hard mass which yielded admirably to milk injections.

Two additional examples selected from my series will indicate the variety of the cases successfully treated by milk injections.

A multiparous woman, whose husband showed signs of subacute gonorrhea, was taken ill with abdominal pain and fever, leucocyte count 18,500, polymorphonuclear 82 per cent. and was admitted to the hospital with acutely inflamed adnexa and an exudate in the posterior cul de sac. Repeated smears from cervix and meatus were negative for gonococci. The complement fixation of the blood was also negative.

Another multiparous woman came under my observation about three weeks after a normal delivery. She had been a ward patient in a well organized maternity hospital and, on the twelfth day, being apparently in good health, she had left that institution. Immediately upon reaching home she was taken ill and remained at home with nearly no medical care until her admission to another hospital where she was under my care. She appeared to be extremely sick, temperature 104 and 105°, leucocyte count 20,400, polymorphonuclear 78 per cent. There was an exudate in both broad ligaments. Several injections of milk were given. An absolute cure resulted.

In both of these cases when all acute symptoms disappeared the milk treatment was supplemented by hot douches and baking.

In the entire series of cases I used milk in the form of aolan, beginning with the injection of 5 c.c. and then increasing after the second or third injection to 10 c.c. In the majority of my patients the reactions after injection were much milder than those described by Gellhorn or some of the other observers who used ordinary sterilized milk with its naturally high bacterial count. Most of my patients complained of malaise to a greater or lesser degree, at times of pain in abdomen especially in that part where the lesion was greatest. It was only in the very sick patients that the first injections were followed by a marked rise in temperature. The majority of the patients showed great improvement with the first two or three injections, or else at least an arrest of the process of infection. The leucocytosis was always increased two to five thousand with the initial injections. This increase invariably appeared within six hours after the injection and within twenty-four hours disappeared gradually, until the preinjection count was reached. The leucocyte number usually changed little after the third injection.

Within twenty-four hours after the initial reaction had worn off, the patients often showed remarkable improvement. They rested better, partook more readily of food and in general became more hopeful. There was an appearance of well being and bodily comfort. In many cases that had not previously yielded to different kinds of treatment the improvement in general and local condition was amazing. The exudate at each examination appeared to be melting away. In some patients, however, the lesions proved to be more obdurate.

In none of my cases were there marked local reactions at the point of injection. The injections were administered intramuscularly in the buttocks at intervals of three to four days; later in the treatment these intervals were lengthened to seven days.

As I mentioned above my cases were acute when they came under my observation; most of the patients had been ill a few days or perhaps a week, except one who had suffered for a year, having exacerbations at the menstrual periods. Upon vaginal examination this patient presented in each laternal fornix a mass that was shading into the surrounding tissues. The left mass adhered to the rectum and could be felt bulging into it. There was marked rigidity, high fever, leucocytosis of 12,200. The patient vomited, had a sense of pressure in the rectum and seemed acutely ill. After several injections of milk (aolan) the subjective symptom subsided except for the sense of pressure in the rectum and the frequent desire to evacuate the bowels. The temperature dropped, rigidity disappeared, and on vaginal examination the masses in the lateral fornices became more clearly defined. A diagnosis of bilateral tuboovarian abscesses with the left one pointing into the rectum suggested itself. This was corroborated by operation, when a double tuboovarian abscess was removed with a pus pocket on the rectal wall. The patient made a speedy recovery. The postoperative course was unusually mild, perhaps because of the milk injections.

Previous to the milk injections, the first few patients of the series received intravenous injections of colloidal iodine in the form of a preparation called mirion and also one injection each of 5 c.c. of electrocollargol. These introductory injections seemed to exert no beneficial influence and consequently were abandoned in the later cases. The altered form of treatment, i. e., without the colloidal preparations, gave the same favorable results.

I saw those colloidal preparations used in European clinics in puerperal cases or after abortions on patients that were thought to be potentially infected; these were frequently women, who had been subjected to many examinations during delivery as in difficult forceps or in other intrauterine manipulations. Many had been treated outside of the clinics and had been brought in after unsuccessful attempts at delivery in the home. Many had been attended by midwives. Such cases received the colloidal injections rather as a prophylactic than as a curative measure. Those patients which I treated, on the other hand, came under my care not earlier than the third day of illness; most already had high fever and all signs of local or general peritonitis. Thus it is likely that the apparent failure of the colloidal preparations in my cases was due to the fact that the pathological changes were too far advanced to be influenced by the metallic colloids. These substances are administered as follows: Mirion is injected intravenously as follows:—first day, 0.5 c.c., second day, 1.0 c.c., third day, 1.5 c.c., fourth day, 2.0 c.c., fifth day, 2.0 c.c. A half hour after the last injection five c.c. of electrocollargol is administered intravenously.

Ordinary milk may be used if it is boiled in a water bath for ten minutes or pasteurized in an autoclave. Certified milk used after the usual boiling or pasteurization causes less violent reaction than common milk, without diminishing the efficiency of the results. This is said to be due to the relatively low microorganism content of certified milk. Milk does not cause perceptible local reaction when the fat has been removed by centrifugation. It is believed that the fat, because it is slowly absorbed, acts as a foreign body and hence causes severe local reaction. Many observers maintain that the rapid febrile reaction is the healing factor and that injections are followed by marked leucocytosis.

SUMMARY AND CONCLUSIONS

Injections of milk were made preferably in the gluteal region. The initial dose was five c.c., in very sick patients even less, and other injections followed at intervals of three to five days until all signs of the lesion disappeared or until the localization and improvement of conditions indicated operation. In my series of cases each patient required from three to eight injections. In cases that ultimately require operation, a preliminary course of milk injections localizes the process, renders operation easier and makes the postoperative course not nearly so tempestuous as is usually the case. Most of the patients did not exhibit severe reactions, the leucocytosis being not excessive and the course being entirely undramatic. Despite this, great strides were made toward recovery. Hence I infer that severe reactions after injection are not essential for cure. The physician must not forget fresh air, diet, or other supplementary methods of treatment.

The injection of milk proved to be of great value in my cases of pelvic infection and I recommend it to clinicians for further observation and study.

Obstetrics and the Future

HERBERT THOMS, M.D., F.A.C.S.

New Haven, Conn.

Oliver Wendell Holmes, a noteworthy contributor to modern obstetrics, once said: "The great thing of this world is not so much where we stand as in what direction we are moving." When we survey our present day position in obstetrical science we may be said, in the happy phrases of the columnist, to both "point with pride" and "view with alarm." Such great gifts to humanity as those of Simpson and Semmelweiss cause us rightfully to lift our heads in the pride of their achievements, but, on the other hand, our acknowledged helplessness in the severe infections and toxemias makes us realize that in other fields our progress is but begun. Yet who is there today that does not earnestly believe that even these problems will some day be overcome? Scientists have ever properly ignored the "when" element in order to concentrate their effort on the "how."

Occasionally, however, it may not be wholly without profit to consider a time when these and others of our present day difficulties will have been solved. A stimulating and somewhat startling essay of this nature has recently come from the pen of a British scientist, Mr. J. B. S. Haldane. In his brochure, *Dædalus, or Science and the Future,* he has shown us in a not unentertaining manner some of the things that our race may expect in the far future, particularly in the field of genetics. One may spend a delightful hour carried on the wings of this author's imagination through the realms of ectogenesis and its phases of human application. This essay has a particular interest to obstetricians because they represent a group of medical scientists in whom the problems of race reproduction are ever imminent, and while many of the deductions of Haldane appear absurd, the most conservative scientist has learned today to admit possibilities for the future, even in such strange fields.

It is pleasing to speculate from the obstetrical point of view in the light of our present day knowledge what developments we may expect in our special field. Our imaginings may be but the first footsteps toward that extraordinary sphere pictured by our British colleague, but they are interesting nevertheless. Among the first things, we may expect with some certainty that thorough physical examinations will be required of both sexes before legal marriage is permitted. After this, if not before, microscopic and serological tests will demonstrate the question of the fertility of the union. Already in this field we may be said to have made an auspicious beginning. Before the inauguration of reproduction an examination of the prospective mother by physical, laboratory, and x ray methods will give exact knowledge of her ability to bear children. Even today this question has become of considerable importance. By means of the x ray and other physical agents we may now measure accurately the bony passages through which the child must pass, and by means of the laboratory and other tests the potential ability of such vital organs as the heart and kidneys may be determined. Reliable function tests for other organs, particularly the all important liver, unquestionably will soon be established. In the future all of these studies and others will be correlated with psychological studies of the individual so that proper motherhood will be entered upon by suitable persons.

The question of birth control, as the regulation of conception is commonly called, is already being settled. To anyone familiar with practices common in the educated classes today, the answer is certainly not in the negative. The problem, therefore, is but an extension of this knowledge to the masses. In the future, regulation of conception will be scientifically practised, and the race will then probably wonder why this ever was a debatable question.

In considering the problems of sterility, who doubts that the knowledge gained by our successful breeders of plants and animals will be eventually extended to the culture of human beings? For instance, artificial impregnation of the human species has been already successfully reported by numerous men in cases where natural impregnation failed to take place. The use of this measure in animals, particularly mares, is well known. In the future, knowing the date of insemination, by serological and other tests we shall know accurately when impregnation has taken place. The pioneer work of Abderhalden and his followers has begun the

solution of a problem which must certainly have a definite answer.

We may furthermore confidently believe that the complications of pregnancy that we now know will be eventually overcome and the prenatal period always act as that splendid stimulant to good health which one so frequently observes in individuals today. The activity and general mode of living of the prospective mother can and will be regulated so that this period of her existence will be looked upon as a normal, healthy process, and it will be also endowed with the sanctity that properly belongs to it. Our present prenatal activities are but the first steps.

Not only is it reasonable to believe that the sex of the offspring will be determined early at some future time, but one will be also able to predict whether a certain union will and will not produce dominant characteristics inherent in the parents. It is within a quarter of a century that our laws of heredity have been definitely formulated, but we should not forget that three hundred years ago Francis Bacon, in speaking of experiments in genetics on the famous island of Atlantis, wrote, "neither do we this by chance, but we know beforehand of what matter and commixture what kind of those creatures will arise." Even these things, therefore, are not new under the sun of our day.

The period of labor (probably another name will be substituted) will be approached with exact knowledge as to the time and cause of this phenomenon, and the patient enter a special institution for this event but a few hours before birth. The entire process will be, of course, painless. The array of agents used at present, nitrous oxide, ether, chloroform, morphine, scopolamine, magnesium sulphate, and spinal anesthesia, all represent attempts at the solution of a problem which has a final answer. It is quite probable that some modification of the last named will be the solution. This is stated in view of the fact that nerve blocking has been so successful in other parts of the body, and it is furthermore desirable because consciousness may be retained.

With regard to operative procedures we may expect that these will be performed even in a most distant day because disproportion will occasionally exist. One might, of course, imagine that by careful mating the size of the offspring might be regulated, and also the possibility of glandular therapy in early life and its influence on the formation of the bony pelvis might be thought of.

When we are brought to consider the great problem of obstetrical care for the masses in childbirth we see but one solution and that is the establishment of proper hospitals or institutions for this purpose. The care of women at home will always be an economic waste of time, material, and lives. With increased knowledge of the processes concerned in impregnation and pregnancy we shall have definite knowledge not only of the cause of labor but also of the time of this event. The problem for the rural districts becomes then principally one of transportation. These hospitals will probably be established and maintained by the state, for it will be eventually realized that good citizenship begins with proper motherhood. We may further expect that that these institutions will be something of the sort described so many years ago by Sir Thomas More, who, in the early part of the sixteenth century, wrote: "So well appointed and with all things necessary to health so furnished, and moreover so diligent attendance through the continual presence of cunning physicians is given, yet notwithstanding there is no sick person in all the city, that had not rather lie there than at home in his own house."

It is quite apparent to anyone familiar with the excellent midwife system in use in the larger British hospitals that in the future the care of women in childbirth will be relegated in the main to women trained in this science. Already the number of available trained men would be wholly inadequate to attempt work on any large scale and it is inconceivable that men of inferior medical training would be used. The development of the above named system offers unquestionably the best solution. Specialized surgeons will exist long after disease has vanished from the earth and among these will be those who will attend certain difficult cases of childbirth. This idea is by no means new but actually a reversion to the French system of two hundred and more years ago. The history of the human race seems to be replete with such repetitions.

The feeding of newborn infants in that distant day will assuredly be breast feeding. As the old Hindoo Gautama says, "Like the approach of the iron to the lodestone is the approach of the newborn child to the breast." In spite of our wonderful advances in human nutrition, artificial feeding of the newborn will disappear. From an economic as well as a physiological viewpoint Nature's way will triumph. The important role played by hormones in the inauguration and maintenance of breast feeding is now beginning to be understood. But a little time and if breast milk is not suitable, we shall know how to make it so.

It is a temptation to try and picture the care of the newborn in that far day. In our day the rapid advances in hygiene, nutrition and education of young children are almost bewildering. The eradication of disease, like rickets, scarlet fever and diphtheria which have taken place almost overnight are brilliant beacons lighting the way to successes hitherto unimagined. The great responsibility of the child from birth, then, as now, will belong to the pediatrist, the psychologist and the hygienist. The responsibility of the obstetrician ends with the advent of the healthy child at term.

We have not spoken of the important paternal role in future race production but this will not be neglected as at present. From a physiological viewpoint the father has a definite part to play. He not only has a right to understand fully the process by which his progeny is to enter the world, but his share in the preparation of that event is no inconsiderate one. We may conjecture that in the distant future, number of offspring may have a legal regulation. This will take place not only on a physical but also on an economic basis. We may also assume that family ties will not be swept away as has been predicted. On the other hand, they will be immeasurably strengthened. The privilege of replenishing the race will be looked upon in its proper sphere as a noble obligation. Man's moral growth must keep pace with his intellectual advance.

The foregoing is but an attempt to set down a few random thoughts on childbirth and the future of our race. While our greatest inspiration will be always found in the lives and achievements of those who made possible our science today, yet an occasional excursion like the above may be also helpful. May we not therefore divine that the Great Book has more than a moral meaning when it urges that "we make a stand upon the ancient way and then look about us, and discover what is the straight and right way, and so to walk it."

Extrauterine Abdominal Pregnancy

CHARLES S. WACHS

Philadelphia, Pa.

The abdominal type of extrauterine pregnancy is a comparatively rare condition. When it does occur, it is almost always secondary to a tubal pregnancy which has ended in tubal abortion or rupture without the death of the fetus.

At one time it was believed that the ovum could implant itself upon any portion of the peritoneum and thus give rise to a primary abdominal pregnancy.

Cases of this type have been reported in the literature, from time to time, but careful investigation of many of these have later proved them to be of the secondary variety.

The causes, therefore, of the abdominal type of extrauterine pregnancy would, in most instances, be the same as that of a tubal pregnancy. If a tubal pregnancy occurs and results in rupture or abortion, the condition being undiagnosed and the patient surviving, then an abdominal pregnancy may result, providing the placenta remains attached to the tubal wall or forms a new attachment to the peritoneal contents, thus maintaining its circulation.

Usually when a fetus has been extruded into the peritoneal cavity, it dies and becomes absorbed, unless it has attained a certain size before death, in which case absorption is impossible and the fetus either undergoes suppuration or becomes a lithopedium.

Since pyogenic bacteria often gain entrance into the gestation sac, the former may readily occur and the resulting abscess may rupture into the intestines or bladder depending upon its situation.

When an abdominal pregnancy occurs the usual symptoms of pregnancy persist, with the exception of pain which is present and the fetal movements are felt to a greater extent than in a uterine pregnancy. If the pregnancy goes to term, false labor usually sets in, the pain being similar in character to an early normal labor. These pains may continue for from a few hours to several days and eventually end with the death of the fetus. When this occurs the placental circulation becomes gradually abolished and the amniotic fluid becomes absorbed so that the patient may notice a sudden decrease in the size of her abdomen. After this initial decrease, the size remains stationary, the gestation sac becoming abscessed or the child, after a number of years, becoming mumified or converted into a lithopædium.

TREATMENT

The treatment of extrauterine abdominal pregnancy depends upon the stage in which the diagnosis is made and the condition of the patient. If the diagnosis is made early then operation should be advised immediately. If the diagnosis is made sometime later, the patient being in good condition and the fetus living, operation should be deferred until the child is viable.

If the case is handled properly the chance of a living baby is good. Horsley in 1912 reported a series of 138 cases where living babies resulted in cases of abdominal pregnancy.

At operation, whether it be performed early or late, the greatest danger is in the removal of the placenta. If done early the fetus being dead, removal of the placenta is not difficult, changes having taken place in its blood supply which greatly facilitates its removal.

When the operation is done either early or late, the fetus being alive, some operators advocate the closure of the abdomen without attempting the removal of the placenta and without instituting drainage, while others advise against removal but recommend the insertion of a drainage tube. Those advocating the latter method are in the majority. When removal of the placenta is attempted, in the case of a live fetus, bleeding is usually severe and may become uncontrollable.

Beck has proved by animal experimentation that three fifths of a human sterile placenta can readily be handled by the peritoneum of a dog. He also collected twelve cases of extrauterine abdominal pregnancy where operations were performed at term. In all of these cases the cords were cut close to the placenta and the latter with their membranes left *in situ*, the abdomen being closed without drainage. The mortality rate in these cases was thirty-three per cent. as against thirty-nine per cent. in a similar series where removal was attempted.

In our case partial removal was attempted and bleeding became alarming, packing and tube drainage were inserted and the remains of the placenta allowed to slough away, the patient making a good recovery, although convalescence in the beginning was stormy.

Case I.—Mrs. K., white, aged thirty-six, was admitted to the Mt. Sinai Hospital on March 8, 1925, with a diagnosis of peritonitis, due to an attempted criminal abortion. Chief complaint on admission was severe abdominal pain and tenderness. Past medical history was negative.

She had been married eight years, now a widow, husband died from influenza, two children living and well, no abortions. Until present illness menses were

regular, twenty-eight day type lasting four days, not accompanied by pain, used three napkins a day. Last normal period December 7, 1924.

The patient expected her period January 7, 1925, but it was delayed until January 16th, the flow was unlike her regular menses, being scanty in amount and lasted only one day. She also at this time experienced some nausea and lower abdominal pain. There was no evidence of the period she expected in February and around this time she suffered from several attacks of severe cramplike pains in the lower abdomen, which lasted for several hours.

A physician was consulted who diagnosed an early pregnancy and performed a dilatation and curettage on the patient in his office. After this, the patient bled slightly and suffered from continual abdominal pain. One week later a second physician was consulted who thought the patient was still pregnant.

Mrs. K. then returned to the first physician who again explored her uterus. After the second exploration patient became extremely sick, pains were constant and increased in severity, abdomen became distended and tender, there was extreme weakness and fever. At this time the patient was admitted to the hospital.

Examination on admission showed a well nourished female, who appeared to be very sick. Skin and mucous membrane very pale. Tongue dry and coated. Temperature 101°, pulse 140, respirations 26. The heart was rapid, no murmurs. The lungs were negative. The entire lower abdomen was distended, rigid and tender to pressure with a mass easily palpable in the right lower quadrant.

Vaginal examination showed the uterus slightly enlarged and softer than normal, with a large mass to the right and posterior to the uterus.

Blood examination showed red cells 2,816,000, hemoglobin 46 per cent., leucocytes 15,800, polymorphonuclear cells 81 per cent., small round cells 16 per cent., large round cells 3 per cent. Blood culture at the end of twenty-four hours was negative. The urine was negative except for a trace of albumin.

Taking into consideration the menstrual history, the character of the pains, the blood findings and the vaginal examination a diagnosis of an ectopic pregnancy was made with either rupture or tubal abortion plausible. This diagnosis was further strengthened when, on investigation, we were informed that the uterus, which had been explored on two occasions, was found apparently empty.

Consent was given to an operation. On opening the abdomen a considerable amount of clotted blood was found in the peritoneal cavity and attached to the cecum and omentum was a living gestation sac. The sac was ruptured and a fetus about ten cm. long removed. An attempt was made to remove the placenta but had to be abandoned on account of the excessive bleeding which resulted. Packing and a rubber tube were inserted to control the bleeding and permit drainage. The right fallopian tube, which showed evidence of tubal abortion, was not removed on account of the poor condition of the patient.

Recovery was complete, the patient being discharged from the hospital April 17, 1925, about six weeks after admission.

2017 Pine Street.

Urology in the Female

T. JUD McBEE, M.D.

Morgantown, W. Va.

The close anatomical and physiological relations between the urinary tract and the reproductive organs of the female give rise to many interesting problems in the diagnosis and treatment of what the patient commonly terms "female trouble." The symptoms and signs of pathological conditions in one tract do so frequently resemble those of the other that a careful study must be made before the practitioner can begin a corrective treatment with reasonable expectation of successful results. Indeed the therapy in many cases must include diseased organs of the two systems.

The close relationship must not lead us into thinking that urinary symptoms are always dependent upon some existing lesion of the generative organs. Diseases of the urinary organs occur alone, or in conjunction with, but not dependent upon lesions of the genitals. Diseases of both systems may coexist, be caused by the same factor and yet not dependent the one upon the other.

The physiological changes of the genital organs during menstruation, coitus and pregnancy have their bearing on the urinary tract as have variations in the size and pressure of the bladder on the reproductive organs. Pelvic congestion during menstruation, sexual excitement and pregnancy often causes and frequently increases urinary symptoms.

The conscientious genitourinary surgeon, devoting his attention to urology exclusively, is necessarily more familiar with the urinary organs in both men and women than the gynecologist, who, often combining obstetrics with gynecology, hardly finds sufficient time to acquire, or, having acquired, to maintain a proficiency in all three specialties.

In a review of the anatomy of the female urethra, it will be found that it has much the same muscles, glands and histological tissue as the male urethra. While it is only about one inch in length it nevertheless is the seat of many extremely annoying symptoms.

Stevens in the study of two hundred nonpregnant women with urinary disturbances found that the symptoms were entirely due to urological conditions in seventy-three per cent.

Bugbee in a series of one thousand cases of frequency of urination, which is the most common symp-

tom of which the female complains, found that it was due to urological conditions in seventy-four per cent.

Dannreuther, a gynecologist, reported six hundred of his consecutive cases in private patients in which 119 or twenty per cent. required a cystoscopic examination to establish a diagnosis. He also says that fifteen per cent. of gynecological patients have some "definite lesion of the urinary tract."

A large percentage of what are loosely termed "female troubles" in girls and young women are urological conditions or urological and gynecological conditions combined. (My unbiased opinion would be about fifty per cent.)

In a brief discussion of urology in the female, which is my intention, I cannot take up the urethra, bladder, ureters and kidneys individually and go over the long roll of their pathology and give intelligent interpretations because the disease of one is not infrequently caused by disease in any one of the others.

As an example one finds that stricture of urethra and contraction of the vesical neck often causes infection of the ureters and kidneys and frequently destroying the function of the latter, and vice versa, infection, disease and abnormalities of the kidneys and ureters may cause some of the most frequent and annoying symptoms that are found in the female bladder and urethra. Owing to lack of space it will only be possible to touch upon the most common conditions.

More careful consideration should be given by the general practitioner, who sees the patient first. By a careful examination many of these cases can be successfully handled by him.

When called upon to diagnosis and treat a condition in the urinary tract of the female we must keep in mind that the symptoms of one may be caused by pathology in another. One should start by taking a complete history and making a complete urological examination. Inspection as well as abdominal palpation should be included in the examination as frequently palpable kidneys or areas of tenderness will give us a clue. The examination of the fresh voided and catheterized specimen of urine is important. Pus cells are not as important in the voided specimen of urine as the catheterized but red blood cells are. With a sterile catheter, the urine should be drawn into a long sterile test tube or other sterile receptacle. After viewing it macroscopically, it should be examined microscopically and chemically. The microscopic is by far the most important. Urine culture grown and guineapig inoculations when thought advisable should be carried out. Pus and red blood cells tell us nothing unless we know where they come from, therefore, when present demands further investigation. We will find in many cases our investigation should be carried further. Each ureter catheterized to the kidney pelvis, the character of the flow noted and the specimen collected and examined as above described. Function of each kidney should be taken at the same time.

It is almost a universal custom to have the patient bring to the office some of the urine voided in the morning for examination. Yet of what use is it to learn that the specimen contains ten grains of urea out of twenty grains of total solids to the ounce if the number of ounces in twenty-four hours is unknown? It is an easy matter to educate your patients to collect the urine for twenty-four hours and measure the total quantity and bring a four ounce specimen to the office.

The external meatus may be the seat of any number of conditions that give rise to urinary symptoms. The external urinary meatus may be contracted, strictured, dilated or have a caruncle or polypi. In the examination of the urethra with the endoscope, we may find it strictured or dilated somewhere in its course. Contracture of the vesical neck has caused much invalidism in young girls as well as adults and resulted in many needless operations. This same condition can give rise to residual urine, acute retention and a role of symptoms resembling prostatism in the male. Incontinence of urine caused by dilatation of the vesical neck and urethra is followed by distressing symptoms that are almost unbelievable. Of the two sphincters, the internal or involuntary is the stronger and most important in the female. Infection of the urethra by unclean, rough, or frequently repeated catheterization is usually the condition commonly and erroneously called cystitis, or "cold in the bladder."

URETHRITIS

Simple or nonspecific urethritis is by far the most common urethritis in the female, as should be expected when it is so close to the vagina, vulva and anus. Uncleanliness of the vagina and anus is responsible for many cases of urethritis. We would not be far from correct by stating that the colon bacillus is responsible for fifty per cent. of urethritis in the female.

A woman may have, in fact commonly does have, gonorrheal urethritis without knowing that she is the victim of any disease. She asserts and believes that there is "nothing the matter with her." It is only by painstaking search of the urethra, paraurethral ducts and glands that one can find the gonococcus. Therefore, it is unscientific and morally wrong to fail to prove by the most delicate bacteriological tests the presence of the gonococcus before a woman should be indicted of having gonorrhea.

The gonorrheal urethritis may extend to the trigone and cause a trigonitis but not further as the variety of epithelium changes here and the rest of the bladder is not favorable to the growth of the gonococcus.

In the cystoscopic examination of the bladder, we must note its capacity. Many misleading symptoms are caused by a bladder having an abnormally small capacity. The appearance of vesical neck, trigone, the ureteral openings, their size, shape, number and whether in normal location and appearance. Observe the mucous membrane of the bladder looking for trabeculations, diverticuli, ulcers, calculi, foreign bodies and tumors. Trigonitis is the cause of pain, frequency and irritability that is so often erroneously called cystitis. It is not a cystitis at all but a trigonitis.

The Almighty has given the female a poor organ for a bladder. In this he may be forgiven for he was not expected to know of the distortions it was to receive from without and its cavity a storehouse for anything from hairpins to the crucifix, besides being bathed with diseased products.

If I believed I had made a diagnosis of gonorrheal

cystitis or diagnosis of any primary cystitis, *per se*, I should hesitate to report it for the unfavorable criticism it would invoke. It is not unusual to hear (in meetings) a physician say in discussing his patient "that I treated her for many months for cystitis without relief." In this he is not bringing anything new to his fellows.

Cystitis rarely, if ever, occurs as a primary infection. Primary cystitis is not accompanied by temperature elevation. Always examine the complete urinary tract first for the cause of the cystitis. If not found there, look further for foci of infection. The cystitis will take care of itself if the cause is removed. Therefore, one can say without reservation that treatment of cystitis by bladder irrigation is a menace unless carried out in conjunction with the treatment of the cause thereof.

Catheterization followed by chills and fever is most always due to previous existing pyelonephritis. This applies to both male and female. Bacteria may be injected into the bladder without causing infection even in cases where trauma exists. It is remarkable how long a bladder will throw off infection in the absence of residual urine.

Any surgeon who elects to do the Kelly operation for incontinence or that for repair of vesicovaginal or uterovaginal fistula should be thoroughly trained in the use of the cystoscope or his results will be far from that which is desired.

ELUSIVE OR HUNNER'S ULCER

Genitourinary surgeons are familiar with the large number of patients with urinary symptoms who have been subjected to various abdominal and gynecological operations, without relief. In the female elusive or Hunner's ulcer of the bladder and stricture of the ureters is probably responsible for more mistakes in diagnosis than any other condition.

In elusive ulcer the female is more frequently attacked than the male. Of the symptoms, the most prominent are frequency and pain and mostly at night. They can only be diagnosed by the cystoscope and then only by one especially trained in looking for it. Best treatment is by direct application of silver nitrate and fulguration.

HEMATURIA

Since we are about to leave the bladder, we will consider hematuria. It may occur without symptoms or with pain and colic. Essential or idiopathic hematuria is but an expression of our inability to determine the cause and to gloss over the neglect to give the patient benefit of a complete examination. The fact that every cause cannot be determined is no excuse for not giving all of them a trial.

Hematuria is often intermittent and when it ceases the patient and physician are often lured into a sense of false security and the opportunity for early recognition of the pathology in its incipiency are often passed and in some instances the condition is beyond relief. A good axiom to be governed by is that every case of hematuria should be considered a grave pathological condition until proved otherwise. Even a few microscopical red blood cells in the urine should be considered grave until proved otherwise. The best time to examine a patient with hematuria is while the attack is on for then the cystoscopic examination will often establish the source and the cause. Character and shape of the clots are suggestive of the source.

Kretschmer reported 933 consecutive cases of hematuria in which he found that 331 were due to lesions of the kidney and 307 were due to lesions of the bladder. In hematuria of the bladder origin tumor is the most frequent cause.

STRICTURE OF URETERS

Strictures of the ureters are one of the most common lesions occurring in the abdomen in women and the man in general practice can make a most probable diagnosis if he will keep the symptoms in mind. The most common are:—frequency, dysuria, hematuria, nagging backache, ureteral and kidney colic, often resulting in hydroureter, hydronephrosis, and complete destruction of the kidney. In a large percentage of ureteral strictures the symptoms are referred to the bladder. A great many have urethral pathological conditions as well. Any of these conditions and particularly that of backache can be relieved by the simple procedure of dilating the ureters. Of those who are skeptical about ureteral strictures I would suggest that you ask some patients what they have to say about the relief they get from treatment. The patients having suffered from ureteral strictures are the best advertisers. It is a good rule to follow before advising operative procedure in obscure abdominal and pelvic pain in the female to have the ureters dilated. Large tumor masses have been caused to disappear by this simple procedure. No better reason for this exists than the appearance of many scars on the abdomen of females with ureteral stricture.

URETERAL AND KIDNEY CALCULI

It is a safe assertion that sixty to seventy per cent. of ureteral calculi pass spontaneously. Nature should be given a full opportunity augmented by interureteral manipulation through the cystoscope with ureteral catheters. This manipulation of one or more catheters inserted in ureters and left for several hours or over night, at regular intervals. It is surprising indeed, the size and number of stones that can be removed in this way and the patient not losing time from work. Crowell reported that out of thirty-one cases of ureteral calculi, twenty-nine were removed without any operative procedure except through cystoscope. Many others have reported like success. Vesical calculi are infrequent in women due to short and often large calibred urethra. When present they are mostly in diverticulated bladders or in cases of large cystocele and incomplete emptying of the bladder at each voiding. It is not uncommon to find vesical calculi in young girls. Stones in the kidney pelvis usually cause more damage than in other parts of the kidney. In examination of patients suffering with calculi, one will find them bilateral in about every sixth patient. Calcified glands, enteroliths, and phleboliths cast a shadow that can only be ruled out by stereoscopic pictures after the x ray catheter is in position.

PROLAPSED KIDNEY

As a rule kidney prolapse is simply an easily identified participant in a general visceroptosis. When a kidney prolapses as far as the true pelvis, however, there are two definite indications for radical corrective measures; Deitl's crisis and damage to renal his-

tological structures. Even then it is no use doing a nephropexy if the kidney function is destroyed.

KIDNEY TUMOR

The most common tumor of the kidney is a hypernephroma. It is a type of papillary carcinoma which is peculiar to the kidney. The slow growth of tumors in the bladder and kidney is peculiar to these two organs. Renal tumors of childhood belong to sarcomata class and grow very rapidly.

Failure to make an early diagnosis is due to:

1. Lack of appreciation of the significance of hematuria.
2. Inability to recognize the presence of small growths by physical examination.
3. Failure to consider renal tumor in the differential diagnosis.
4. Failure to appreciate the significance of small filling defects in the pyelogram. The changes in the size, shape, and contour of the pelvis and calyces can be decisively demonstrated in the usual pyelogram.

Hematuria is by long odds the most important symptoms of renal tumor and may extend over a period of years.

TUBERCULOSIS OF URINARY TRACT

Tuberculosis of the urinary tract should be suspected in a woman when the bladder is intolerant of even bland fluids; if the urine is persistently acid, or the capacity reduced to four ounces or less; if there is more involvement of one half of the trigone than the other, or there are obstinate ulcers on the bladder wall or marked distention of the ureteral orifice.

In any patient between the ages of fifteen and forty with pyuria of an apparently causeless nature continuing over a period of two to three months with frequency, nycturia, dysuria and acid urine, that proves negative to microorganisms by the ordinary staining methods one should search for the tubercle bacillus. Repeated examinations should be made together with guineapig inoculation.

In renal tuberculosis there are practically no urinary symptoms until the process has extended to the pelvis. Pyelitis and vesical symptoms promptly follow. Pregnancy aggravates urinary tuberculosis and if only one kidney is affected, it should be removed.

COMMENT

Emphasis should be made on the necessity for closer cooperation between the gynecologist and urologist and between the pediatrists and the urologist.

Urinary diseases occur frequently in infants and children and the successful pediatrists of today have frequent use for consulting the urologist in the diagnosis and treatment of diseases of children.

If the gynecologist does not wish to burden himself with the exacting demands of the urological field, he should at least be closely associated with a urologist, and if the urologist has not been well trained in gynecology, he cannot do justice to his female patients without consultation with the gynecologist.

Affections of one kidney may cause pain in the other—known as renorenal reflex. We are familiar with normal location, size, etc. of the various abdominal and pelvic organs in the female but we must always keep in mind that these organs may wander far from their natural habitat.

Ptosis, sagging of the kidney, kinks or strictures of ureters or the kidney failing to rise from its congenital position, will give rise to marked symptoms, the majority of which may appear to be pelvic. A kidney may be only one half its normal size or three times its normal size, may be an abdominal or pelvic organ and still be a kidney, a functioning one at that and possibly the only one of the two that is functioning. The opposite kidney may be normal in size, shape and location and be nonfunctioning. A kidney, much increased in size and reaching down to the pelvic brim may be a perfectly good kidney and its increased size being only a compensatory hypertrophy.

No abdominal or pelvic condition is ever so acute that an examination cannot be made. Nothing can be more acute than pyelitis, pain in hydronephrosis, calculus, ureteral kinks and strictures, etc., yet nearly all of them cannot only be relieved but cured without an open operation by manipulation through the cystoscope.

Pyelitis of pregnancy is almost always caused by pressure of the gravid uterus. The same cause can be assigned in many instances to hydronephrosis during pregnancy.

Christian Science, osteopaths and chiropractors have been made to flourish by our mistakes in the abdomen and pelvis of women. Not our inability or resources but neglect to use them and our being too esthetic to make proper examination. Symptoms should only be valued as ten per cent., pain at ten per cent. and examination eighty per cent. in making a diagnosis.

One should be guarded in what one says about adhesions causing symptoms and pains in abdominal pelvic conditions of the female. The possibility of remote causes should always be borne in mind and the localization in close proximity to some other organic condition which may be the immediate cause of the symptoms. This is well shown by the frequency with which operations for the correction of retro displacements will fail to cure backache. Backaches are often cured by dilating the ureters.

We must constantly regard the woman as our problem rather than the pelvis and that the genitals are not the whole of the pelvis and that there is nothing north of it. The specialty of urology was made necessary by the general surgeon and gynecologist. Many of them saw the difficulty of making a differential diagnosis of lesions of the urinary systems and the unfavorable results obtained when such was not made that a demand was necessarily made on the profession.

The acid test of surgery is "were the patient's symptoms entirely relieved". Any operation or any treatment that fails of this purpose is one hundred per cent. failure. The only way we can measure the relief given by our operations and treatments is by the followup system of cases. The cystoscope, ureteral catheter, the various renal functional tests are the work of the specialist, and upon them depends almost wholly our well founded belief that accurate diagnosis in lesions of the urinary tract is today not exceeded in any other branch of surgery.

As it has been by cooperation that civilization has made such rapid strides so it will be in medicine that the rapidity with which we advance will be in proportion to the earnestness with which the different branches cooperate with one another. In this way only will the maximum of cures be consummated.

CONCLUSIONS

1. Microscopical examination of the urine and the exudates of the urinary tract is more important than the clinical symptoms in making a diagnosis.

2. Many patients are deprived of prompt relief from symptoms because so many are willing to treat a woman for cystitis without actually demonstrating an inflammation of the bladder. Frequent and painful urination should not be called cystitis.

3. Fever is conspicuous by its absence in all cases of inflammation limited to the bladder.

4. A large percentage of gynecological patients require a cystoscopic examination to establish a diagnosis.

5. A large percentage of ureteral calculi will pass spontaneously after a dilatation of the ureters.

6. Cystoscopy, ureteral catheterization, pyeloureterography and pelvic lavage should be used in the diagnosis and treatment of pathological conditions of the urinary tract in the female infants and children.

7. Any patient with continuous pyuria, frequency, dysuria, with acid urine should be suspected of tuberculosis of urinary tract.

8. Hematuria is present in a large percentage of bladder and kidney tumors. Defective filling of calyces after opaque injection is strongly suggestive of tumor of kidney.

9. The advancement made in the profession of medicine is in direct proportion to the cooperation of the different branches. This is best illustrated in group practice.

10. With the armamentarium at hand today accurate diagnosis in lesions of the urinary tract is not exceeded in any branch of surgery.

Treatment of Uncomplicated Gonorrhea in the Female

HARRY W. MARTIN, M.D.

Los Angeles

The treatment of gonorrhea in the female has more often than not been notoriously inefficient—otherwise the records of general hospitals everywhere would not disclose such a large number of salpingectomies, and residual gonorrheas in the cervix, urethra, Skene's and Bartholin's glands would be less frequent. These patients have for the most part been treated by traditional and inefficient methods usually consisting of douches and tampons, and so generally it seems to have been beneath the dignity of the gynecologist or other surgeon who performs the salpingectomy to bother himself about the details of clearing up the residual gonorrhea. Or again, he is likely to use crude and inaccurate procedures such as extensive burning with the actual cautery which leaves in its wake much scar tissue, distortion, and stricture. Frank Kidd (1) has been probably the first to take up the subject thoroughly, comprehensively and in detail in a scientific and precise way.

In attempting to treat acute gonorrhea in the female, there are several factors to be considered: first, how efficacious is the treatment going to be; second, how can we help to prevent complications; and third, how much can the patient help in carrying on the treatment.

Vaginal douches have proved inefficacious except for cleansing purposes before other medication and for the reaction obtained from the heat in cases with cervical and pelvic engorgement when the hot douche is prolonged at a low elevation. Germicidal solutions used in this manner have been of little value, although astringent drugs that act by controlling vascular calibre have helped some.

Tampons are of some benefit by abstracting water from an engorged cervix; but after a tampon has been in the vagina for even a short time, there is usually a large amount of exudate from the tissues which is partially sealed in the vagina behind the tampon, not only hindering drainage but also precluding or diminishing the germicidal action of the medicament used, both by its dilution and also by the chemical action between the exudate and the germicide.

Vaginal suppositories have also proved of little value for the reason that gelatin melts with such difficulty and the resulting solution possesses small penetrating power. Those with a cocoa butter base, as well as ointments, are unsatisfactory because their greasy base partially prevents the action of the medicament on a moist surface.

Painting the vagina and cervix with silver salts and various other germicides leaves out to some extent the endocervix, and they are usually neutralized almost immediately in the ensuing chemical reaction with the chlorides in the secretions and the proteins.

I have used sprays through a vaginal speculum with various medicaments, including dichloramine T. This particular drug was inefficient possibly because

of the fact that it was an oily solution intended to act on a moist mucous surface; sometimes it caused marked excoriation.

I believe that in order to treat successfully acute gonorrhea in the female, we must have good drainage and, as far as possible, frequent or semicontinuous medication to the vagina with an agent that does not react chemically with the inorganic salts and proteins of normal and pathological secretions so as to convert it into a chemically inactive substance and, at the same time, have so little viscosity and great penetrating power. One substance which most nearly seems to meet these requirements is one of the flavines—usually acriflavine—and in a small series of cases (first attacks), which were as yet uncomplicated by salpingitis, the response shown was remarkable. Its use is attended with considerable inconvenience and, as so many of these young women are not immediately ill and do not take their disease seriously, at least to the extent of following explicit directions if they happen to be onerous, and also due to the fact that they must so very often conceal it from members of the family or persons with whom they live, and the fact that acriflavine, like many other drugs, is so apt to leave telltale stains, it will not be found universally applicable. However, it is far more practicable than visiting a physician's office at least once a day.

TECHNIC OF TREATMENT

I suggest the following technic: In the first place, it must be demonstrated on the patient by a nurse who has been trained to do this properly. Procure for the patient a rubber sheet which is placed on the bed or couch after the manner of an ordinary draw sheet. While this protects the bed, a little spilled tends to run over the rubber in drops. To avoid this, place on top of the rubber sheet a cotton blanket folded and refolded to the size of say two feet square on which the patient's buttocks rest, with the covers pulled down to the ankles. This may be reused many times without laundering. Having first partially filled a glass on a stand or chair alongside the bed or couch with about twenty-five c. c. of acriflavine solution—one to five hundred to one to fifteen hundred in strength—from which glass of solution a Day syringe is inserted in the vagina and gently emptied. (The vagina should have been previously cleansed by a douche.)

If the patient injects this acriflavine solution in the manner described after she has assumed the recumbent position and remains recumbent for at least half an hour, the acriflavine solution will have abundant opportunity to penetrate into the walls and mucous glands of the cervix and endocervix and not be precipitated and rendered inert like most silver salts by the secretions. This procedure carried out twice a day will, in most cases, rapidly relieve the cervical gonorrhea and vaginitis, and this is also true even though it is an old case with salpingitis and an acute lighting up of the cervicitis, although it has no direct effect on the salpingitis. It cannot, of course, have any effect on bartholinitis. But the quicker the cervical gonorrhea can be cleared up without radical measures, the less probable the patient is to have later involvement of either the tubes of Bartholin's glands. Perhaps other drugs may prove equally beneficial. Certainly the silver preparations with the larger colloidal molecules, like argyrol, do not penetrate deeply enough. Perhaps none of the organic salts surpass protargol (which is also more economical in that it can be used in more dilute solutions). It has considerable penetrating power and yet can be used in sufficiently strong solution without irritation, so that the proportion of the drug left over after the remainder of the drug has reacted with the secretions is certainly over fifty per cent. if the solution in sufficient strength is used in liberal quantity. A considerable factor, I believe, is due to the fact that the vagina remains filled (although not distended) for a sufficient length of time to allow penetration into the endocervix and the cervical glands, including the endocervical crypts, and for this reason it seems superior to Kidd's method of simply swabbing with flavine solution, especially if the endocervix is swabbed out from time to time with acriflavin or silver nitrate solution after removing the plug of mucopus, as Kidd and others recommend. Nitrate of silver solution employed in the same way, if not used very strong, would be immediately neutralized by chlorides and proteins and its effect would be very fleeting.

For urethritis, ordinarily the gentle instillation of forty to fifty c. c. of acriflavine solution—one to three thousand to one to one thousand into the bladder through a glass catheter and having the patient urinate immediately afterwards is recommended. The urethra is distended by the act of urination and the flavine solution comes in contact with its every portion.

If a trigonitis and severe inflammation of the neck of the bladder should develop, sometimes even to the extent of causing a terminal hematuria which, viewed cystoscopically, shows often a fibrinous deposition over an excoriation at the neck, instillations of argyrol—about two per cent.—in the same quantities and having the patient urinate immediately afterwards is advised. In a certain percentage of cases, acriflavine fails and then other drugs must be employed.

For dysuria santol oil may at times be of value; but for this distress an abundance of fluids with sodium citrate in thirty grain doses four times a day is more reliable. Food substances which irritate the urethra are interdicted, such as alcohol, ginger ale, asparagus, onions, radishes, cabbage, condiments, pickled or spiced foods, and vinegar. Tea and coffee are beneficial because they are diuretic. Lemonade and most fruit juices are also beneficial; the acids in these are oxidized to carbonates and tend to alkalinize, rather than acidify, the urine (vinegar excepted). Prohibiting tomatoes and other articles of diet containing oxalic acid is entirely unnecessary.

For details of the treatment of gonorrheal skenitis, bartholinitis, or residual gonorrhea in the cervix, intentionally not considered in these notes, the reader is referred to Kidd's monograph (1). To advocate this method of applying the local medicament to the cervix and urethra in early uncomplicated cases has been my only purpose—not to discuss complications or extensions of the disease.

Early Signs of Pregnancy

L. DROSIN, M.D.
New York

I wish to recount here some new phases of early pregnancy which I have gathered during seventeen years of observation on innumerable private hospital and dispensary patients, with a view of discovering new signs. I will only touch upon old signs wherever I have original explanations to offer or wherever I can throw new light on them or whenever, by so doing, I can better emphasize my own signs and symptoms.

As for the objective signs I will limit myself to those only which are elicited by palpation and which appear principally during the first half of the first trimester.

Constipation.—If absent, it will appear, if previously present, it will become increased. In a small number of cases the constipation is spontaneously relieved, even to the extent of producing a mild diarrhea.

Bladder symptoms.—Increased frequency of urination. If this condition has previously existed, it will sometimes become normal. The frequency of urination is as a rule attributed to pressure of the uterus on the bladder, but since this manifestation presents itself before there is sufficient change in weight, size or position to make this possible, and moreover, since in certain cases it even relieves the frequency, it must therefore be explained on a different basis, and the most logical is that it is of reflex, nervous origin; at a later period this may be combined with direct pressure.

Vaginal discharge.—If absent, it will appear. If previously present, it will increase in quantity or it will assume a darker hue or a thicker consistency or all combined. In some cases the leucorrhea will spontaneously disappear if previously present. This leucorrheal manifestation in the very beginning is of less significance in patients who experience a discharge a number of days before the menstrual onset.

Objective signs.—To elicit them a relaxed abdomen is essential, and in order to obtain it the lubricated fingers should manipulate slowly and gently in the presence of an empty bladder and rectum, and particularly the former. But with neurotics and in the case of patients in a state of embarrassment, or in case of pelvic disease, this will not be sufficient, for when told to relax, such patients become more rigid—they are too nervous or they do not know how to relax. For this reason I will tell here my part of a dialogue with a patient of this type during an examination: "Keep hands down loosely at your sides; don't hold your breath; breathe perfectly natural; don't resist—in order to feel your womb I must press my fingers deeply into your abdomen, and when you hold your breath even slightly, or when you resist, this is impossible. To prevent causing you pain and to enable me to give you the information you came for, you must breathe out fully." A pleasant voice and demeanor are helpful. In many cases simply telling patients not to hold their breath is sufficient to cause relaxation.

POSITION

1, Anteversion, and 2, descension: The anteversion is actual, partly on account of the increased weight of the body of the uterus due to pregnancy and partly on account of the early softening of the isthmus uteri, even if this may not be evident on palpation, thus permitting the heavier body to fall forward by means of gravity; and relative, as a result of the descension.

3. Dextroversion: Usually attributed to the presence of rectum and sigmoid on left side and to increased constipation. The position of these organs does not change during pregnancy, and how that could account for dextroversion is hard to understand. As for constipation, women as a rule are constipated more or less all the time, and there is usually no dextroversion in the nonpregnant state, and when present this is not altered after evacuation of the bowels. If it would have any effect at all it would, unless the cervix is held by adhesions, force the whole uterus to the right; or, since the contact of the distended rectum with the uterus is just as apt to be with the left side of the cervix as with the body of the uterus, it would just as often cause a sinistra version; and besides this version continues after the weight of the uterus is sufficient to overcome any displacing effect it might have. (The distended rectum, as well as the distended bladder, often causes an ascensus uteri.) We must look for other reasons, and I would suggest the following:

a. A predisposition being present, gravity and descent operate here the same as in cases of anteversion.

b. It may be held in that position by inflammatory adhesions.

c. The uterine supports may not be of equal length or tonicity, and in the same way that they permit in the nongravid state anteversion and retroversion, they may likewise create a version to the right or left, and there are such cases regardless of pregnancy. But with these we are not concerned now. This condition of the ligaments, if it does not create actual version, causes a predisposition to version, or slight inclination, even if this is too slight to be elicited by palpation. But under conditions of pregnancy, when the weight and size of the uterus is increased, no matter how slightly, it will be sufficient to draw the uterus to one side. This occurrence, however, frequently happens before there is an apparently reasonable increase in weight to effect such a change, so we must look for still further reasons, and they are:

d. Predilection of women to sleep on the right side.

e. All women, unless they are lefthanded, perform their daily activities, such as lifting, carrying, throwing, sewing, hammering, and movements of the like, with their right hands, and every time this is done a pressure wave is started and transmitted downward and across the lower part of the pelvis to the left, where it gets lost, and every time the force of this wave strikes the pelvic organs on the right side, including the cervix, these organs are swayed to the

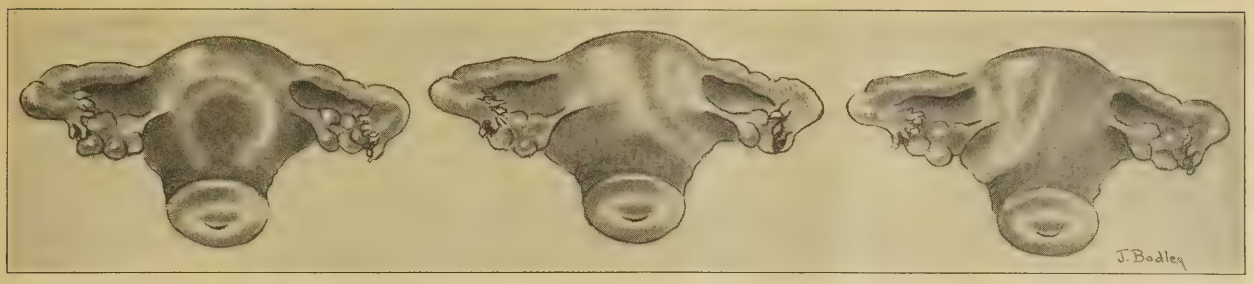

FIG. 1 Fig. 2 FIG. 3

FIG. 1.—Early softening of uterus anteroposteriorly before changes in shape or size appear. Posterior softening not shown.

FIG. 2 and FIG. 3.—Softening beginning at lateral extremities which progress toward the opposite side anteroposteriorly.

left, while the body of the uterus, in consequence, is temporarily swayed to the right, and so a predisposition for the uterus to tilt to the right is created. For the same reason that the right side of the body bears the brunt of the physical exertion and is therefore more perfectly developed than the left side, it follows as a natural consequence that the right tube and ovary are also more developed for their respective functions, and as a result, f, impregnation takes place more often in the right tube than in the left. Consequently hyperemia, relaxation and sagging take place on the right side sooner or in a more marked degree than on the left, so as to permit dextroversion.

4. Sinistra version: Adhesions, conditions of the uterine supports, gravity and descent and predilection for sleeping on the left side and impregnation in the left tube operate here as well as in cases of dextroversion. In women who are lefthanded the pressure wave operates identically the same as on the right side but from left to right.

In conditions of dextroversion or sinistra version prior to pregnancy the action of the pressure wave on the right side or left side will operate to maintain the respective positions, by the impulse of the wave, instead of striking one side of the cervix strikes the whole body of the uterus and cervix, and so helps to maintain the respective versions.

Since dextroversions are so vastly predominant there must be a combination of the above mentioned causes producing them.

Fixation.—In at least thirty per cent. of the cases soon after descent, anterversion or dextroversion has taken place, the mobility of the uterus becomes limited or entirely fixed during the early weeks (or even months) of pregnancy, owing partly to the fact that the uterine ligaments in these cases fail to infiltrate proportionately to the softening and enlargement of the uterus.

Shape will be described in conjunction with consistency and enlargement.

Enlargement.—This goes hand in hand with one or more subjective symptoms and one or more objective signs and may consist of a progressive enlargement with changes in shape or simple increase in size with the original contour of uterus retained. Before the cardinal signs of pregnancy appear the enlargement is as a rule more marked laterally, diagonally, or anteroposteriorly, or in combinations of these; but in the class of cases where the original contour is retained, the uterus is as a rule at first so uniformly, tensely cystic that the isthmus and supravaginal portion are also distended; but the infravaginal portion, or more properly the portion below the flexion or below the internal os, does not yield readily to this distention, and as a result of the anteversion and tension above and the resistance offered anteriorly at the flexion but more particularly at the internal os, where the tissues are more developed and of firmer consistency, the rest of the cervix bends sharply forward, forming an acute angle with the rest of the uterus, and in consequence of which the longitudinal diameter of the uterus is increased out of proportion to all the others and the cervix is reduced to the size of one half inch or less, and more particularly so, its circumference.

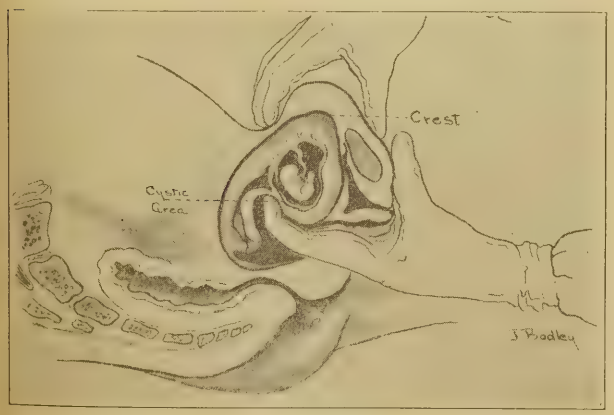

FIG. 4.—Shows cystic area and other features as described under heading of "softening at lower uterine segment." Also crest, ridge or eminence formed by the continuation of the fibres of the tubes, uteroovarian and round ligaments.

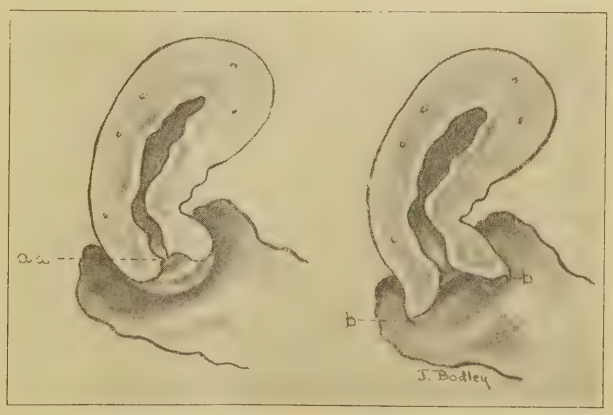

FIG. 5.—aa Represents the edge formed at the junction of the vaginocervical mucous membrane with the lining of the cervical canal within the external os, in intact cervices. bb is the same as aa in cases of torn cervices with eversion. Looking from within outward is shown the band spanning across the angle of the tear.

Consistency.—Hegar's sign; softening of cervix. Before the consistency of the uterus becomes uniform certain portions of it soften first, and I will begin with the one which is considered the most important, i. e., Hegar's sign. The majority of textbooks varyingly describe this sign as consisting of a marked compressibility or softening process of the lower uterine segment at its junction with the cervix, or it includes the supravaginal portion of the same, and others describe it as a marked softening of the isthmus uteri, and they all lay so much stress on its presence and on the methods of its elicitation that one gets the impression that it is the earliest, most constant, and most reliable sign of pregnancy.

As it is thus described, this sign is of but trivial and doubtful diagnostic value, as such a condition, or one closely similar, is present in many apparently normal and healthy nongravid uteri, in many postmenstrual and postabortive states and in many unhealthy uteri where the cervix, isthmus, and corpus are of even consistency, and in most other cases where there is no organic flexion. In other words, where the bend at the corpora cervical junction is only relative, that is instead of forming a sharp angle it consists of a soft angle or a curve; or there may be a complete absence of an isthmus uteri and the body and cervix form more or less of an elongated cone, or the lower segment and cervix simply form an appendage to the body, and the only landmark between the body and external os is the narrow convex or concave border ring constituting the internal os, the position of which is inconstant and bears no relation to the isthmus uteri if present or to the cervicovaginal junction and may be located at, above, or below either one. This also helps to explain the uselessness of McDonald's sign, which consists of ability to turn the cervix on the anterior wall of the body of the uterus.

In the aforementioned nongravid class of cases I was, in addition to turning the cervix on the anterior wall of uterus, also able to straighten the cervix so as to correspond with the longitudinal diameter of the body of the uterus, and in many cases I would extend it far enough posteriorly without effort so as to reverse the flexion. The softening which constitutes Hegar's sign I consider, in the absence of conditions where it is normally found, of value only in cases where there are *a firm corpus uteri above and a firm cervix below,* with the circumference of the intervening part unchanged or increased (and frequently the whole flexion or isthmus, if previously present, obliterated, forming a cone shape), but of such cystic, edematous or doughy consistency as to apparently disappear under gentle pressure. Above the softening merges gradually into the body of the uterus or it terminates in a line of demarcation which is continuous with the rest of the uterus, and as pregnancy advances this line of demarcation rises to a higher level until it disappears in the general softening process. Below, in the early stage, it embraces part of the supravaginal portion of the cervix, and later all of it, thus converting the cervix into a short stump; and later the infravaginal portion, and particularly the portion forming the external os, unless prevented by the presence of scar tissue, is also softened. At this time there is, as a rule, already present a general softening and enlargement, and Hegar's sign, if still present, is of corroborative value only. In case of a normally generally soft uterus Hegar's sign is of value only in the presence of a cystic bulging higher up, anteriorly, sometimes posteriorly and occasionally laterally, with harder demarcation limits; and here it is superfluous. Not infrequently we find the anterior half of the cervix softened as just described and the posterior half very slightly changed or not at all. This condition takes place principally in those cases of marked anteflexion where the lower portions of the body of the uterus and the upper portion of the cervix, posteriorly, form an area harder than the rest of the uterus, a condition which is frequently present in cases of primary sterility; in some retroflexed uteri this condition is present anteriorly.

Softening of the cervix, of a quality attributed to that of Hegar's sign, which may be a continuation of the same, even if it has already disappeared at this period, or independently of it as a result of softening higher up and elicited by bimanual examination in the same manner as Hegar's sign, is, in selected cases and in conjunction with other signs, significant of pregnancy.

It is taught and universally believed that softening of the cervix is one of the early signs of pregnancy. As already mentioned herein, all normal and healthy uteri have soft cervices and, as a rule, of the same consistency as the body of the uterus. But there is no primary softening due to pregnancy. If found, it has been soft previously or is secondary to softening higher up. The truth is that in most multiparous cervices and in all markedly flexed primiparous uteri the cervix is harder than the body of the uterus and is the last part of the uterus to soften, and when it does it is always in a proportionately less degree than the rest of the uterus.

Softening at lower end of corpus uteri.—Frequently, particularly in anteflexed uteri, there may not be any softening on superficial examination, and the softening can only be elicited by fixing the uterus between internal and external hand and following and gently forcing the tips of fingers from the cervix up the lower uterine segment upward in the direction of the fundus, where a cystic consistency will be elicited. It can be illustrated by a cone with firm walls filled with fluid, and this fluid can only be felt through the lower open pointed end. In its anterior aspect is a more or less hard line of demarcation, which is continuous with the rest of the uterus anteriorly, but posteriorly it is soft or hard and without a line of demarcation; or, to be more exact, this picture can be compared to the back of the head and neck representing the anterior surface of the body of the uterus and cervix respectively, the finger pressing into the nape of the neck upward into the foramen magnum where the cystic area is felt, and the occiput and adjacent surface representing the hard line of demarcation continuous with the rest of the anterior wall. At a somewhat later period the harder bulging of anterior wall corresponding to the occiput also becomes cystic with harder borders of demarcation, the anterior surface becoming either more convex or flat or concave if softening is more marked posteriorly with the resulting increase in the lateral diameter and, as a rule, more to the right than to the left. Less typically this cystic manifestation can sometimes be elicited on the right or left side of the uterus.

Here I wish to add that all the varieties and degrees of uterine softening are represented by the consistency of the anterior fontanelle in different newly born children during states of rest, straining or crying.

There are still other signs elicited by palpation which occur frequently and which are pronounced and reliable, and a very prominent one is a projecting mass from the right side of the uterus, sometimes taking the shape of a walnut and at other times of a butternut of varying sizes, and as a rule harder than the rest of the uterus, but occasionally softer, the lower border of which starts on a level with the isthmus or internal os and extends outward and downward forming more or less of a triangular space between it and the cervix. The clearness and readiness with which this sign is elicited is partly due to the dextro and anteversion of the uterus which is present at this time. Internally and above it merges into the body of the uterus with a more or less marked line or groove of demarcation. Coincident with this, or separately, the left cornu is also harder and occasionally softer than the rest of the uterus and extends, though less prominently, in a direction upward and outward.

Softening of lateral extremities of uterus.—Softening may start at extreme right or extreme left edge of the body of the uterus, with line of demarcation (in this case it is flat on palpation) and extends toward opposite direction anteroposteriorly, joining with the opposite side at or beyond three months of gestation. The lines of demarcation shift with the extent of the softening and may be marked or gradual according to the consistency of the uterus.

Softening of the anterior wall.—It may be present at a soft circular or ovoid shaped area on the anterior wall of body of uterus with a harder border of demarcation, the lower border of which soon becomes illdefined and terminates at some point in the lower uterine segment, with no other change in shape, size or consistency until this softening increases; or the softening may start in the upper end of anterior wall, and in these cases it presents an anterior cystic convexity.

Softening of posterior uterine wall.—As a rule the softening process of the anterior wall is simultaneous with that of the posterior wall, but it is apparently less marked posteriorly on account of its more difficult accessibility and on account of the frequent early, exaggerated anteversion, with the resultant gravity of the circulation and of the ovum, or of either, anteriorly, the anterior wall is more bulging than the posterior, and the latter, therefore, seems relatively flat; but by obtaining sufficient control the posterior wall is usually found very soft.

Softening of the lower or middle part of the posterior wall of the uterus, when softening anteriorly is doubtful and the uterus cannot be brought forward, can be elicited by forcing the body of the uterus backward and downward and following finger up posteriorly above the isthmus. Frequently the softening and bulging is more marked on the posterior wall, and in these cases the anterior wall feels concave or flat. When the softening begins in the middle of the uterus anteroposteriorly before there is any palpable bulging the lateral diameter is increased (and more to the right than to the left), and the anteroposterior diameter. while yet unchanged, or even when somewhat enlarged, feels relatively narrowed. Frequently the anteroposterior softening is so uniformly eccentric and the rest of the distal portion so little changed in shape or consistency that it forms, with the exception at the isthmus, a perfect border around the softened area.

More or less uniformly rapid enlargement and softening of the whole body of the uterus takes place in conditions of marked anteflexion or in other cases with cervices of unusually hard consistency.

In most of the chronic subinvoluted or fibrotic uteri, with their characteristically hard consistency, the very first objective indication of pregnancy is a superficial, uniform softening of the entire uterus, which soon deepens and then becomes either uniformly cystic or irregularly nodular with edematous or cystic zones between the nodules followed by changes in shape, size and position. This is the class of cases in which early diagnosis is most difficult.

Fundus uteri.—The continuation of the fibres combining the tubes and uteroovarian and round ligaments forms a well defined palpable ridge or crest or eminence running across the transverse diameter of the fundus of the uterus, which always draws a line of demarcation between the anterior and the posterior walls, becoming more pronounced during pregnancy on account of subjacent softening, and is usually painful to palpation at the cornu corresponding to the side of maximum softening of the body of the uterus and does not, as a rule, entirely disappear up to a period beyond three months of gestation. Its location is toward the posterior aspect of fundus when softening is more pronounced anteriorly, and toward the anterior aspect when softening is more marked posteriorly. Postpartum this crest is the first thing to reappear and frequently it does so with the expulsion of the fetus and placents.

Mucous membrane at external os.—When the uterus has softened sufficiently to involve more or less the whole cervix, which not infrequently happens during the period within the scope of this article (but as a rule at a later period), the mucous membrane of the vaginal portion of the cervix at its junction with the mucous lining of the cervical canal can in the majority of cases, while gently moving finger from within outward and from without inward, be felt as a soft, thin, yielding, and somewhat detached edge, just within the external os or on the external edge of it at a later period and in cases of eversion. In cervical tears with little or no scar tissue this sign can be felt in the angle of it as a thin band spanning across it, with the edge soft, yielding and detached as above, and appears much sooner than at the portion of the original external os. I never found this sign present in any other condition than pregnancy. I have, however, met a somewhat similar condition in the nonpregnant state in cases of torn cervix with eversion and induration of the lips and in a number of cases of cervical polypi; but here it was present as a well defined, comparatively thick, tense, unyielding, and undetached edge or membrane, which could in no way be confounded with the one of pregnancy.

Mucous lining of the cervical canal.—During the period that the edge formed by the cervical mucous membrane appears, or coincident with its presence,

the mucous lining of the cervical canal usually takes on a finely or roughly granular softening on palpation, which breaks down upon touch or slight pressure with the palmar surface of finger and the moment this takes place an impression of a low toned, short, crepitant or crackling sound is conveyed to the mind. This impression should not be confounded with the scratching or tearing sound caused by the rubbing of the nail against the tissues.

GENERAL CONSIDERATIONS

In the beginning of pregnancy there may not be any subjective symptoms, or there may be one or more; the same thing holds true of the objective signs. There is present, as a rule, a combination of the signs and symptoms.

Although the subjective signs and symptoms may vary with each pregnancy—but during the period of pregnancy under consideration they are more or less constant—the objective signs, on the other hand, during the same period are inconstant. A certain sign being present on one examination, on the following examination, while there may be an elaboration of the same, it is just as likely to be found to be ill defined, covered, or obliterated by new signs as a result of the constantly progressive process of softening and growth; and these processes in turn are in a measure inhibited, modified or controlled by the contractions and relaxations of the uterus, but more so by the irregular, incomplete, and slow contractions and relaxations, and in some cases instead of finding a certain sign in the same location, it may be situated in a modified form in a diametrically or directly opposite position, or in more than one position, or instead of finding part or all of the uterus in an increased state of softening, it may be found to be of a firmer consistency, and instead of an increase in size there may be none, or it may even appear smaller than previously, but on the whole seldom losing the characteristic consistency of pregnancy; frequently a later examination may have to be made.

The proper elicitation of the objective signs and their correct interpretation is largely dependent on the amount of deliberation, gentleness and slowness with which the manipulations are carried out.

To those with little or no experience, more than one examination cannot be too strongly urged.

1851 SEVENTH AVENUE.

Glucose as an Oxytocic

M. PIERCE RUCKER, M.D.
Richmond, Va.

There are two classes of oxytocics, those that strengthen normal rhythmic contractions and those that produce abnormal contractions of the uterus. Pituitary extract is a typical example of the latter class, for even in the smallest doses it produces an incomplete tetanus, i. e., one contraction after another without any period of relaxation between. Glucose is an excellent example of the first class.

Bossi (1) in 1893 called attention to the ecbolic action of sugar in cases of inertia. Vignes (2) explains its action on the supposition that sugar replaced the reserve glycogen that was used up in the course of labor. Several years ago (3) I began the use of glucose, given as an enema, more or less routinely with the idea of avoiding the exhaustion and the inertia incident thereto. The results were extremely satisfactory, and the first stage was materially shortened, and the patients finished their labor in excellent condition.

I have a great number of hysterograms which were obtained from patients while a five per cent. glucose solution was being administered per rectum and in no case has there been abnormal contractions of the womb. Fig. 2 is a typical example of such contractions. Opportunity of showing graphically the action of glucose upon an exhausted uterus only recently presented itself. Fig. 1 is a hysterogram obtained from a patient with hyperemesis gravidarum. She had lost considerable weight when she entered the hospital. Her pulse was constantly above

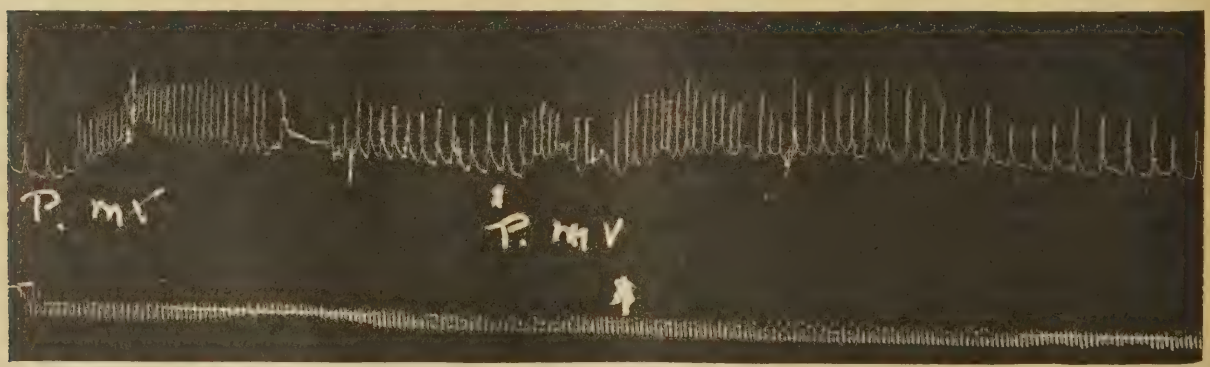

FIG. 1.—Hysterogram of patient in fourth month of pregnancy. 5 m. pituitrin were given at points indicated, and a proctoclysis with five per cent. glucose solution was started at point indicated. The first dose of pituitrin caused a characteristic pituitrin effect. The contractions followed one another without pause so that the intrauterine pressure was increased. The second dose of pituitrin had only slight effect on account of exhaustion. The glucose quickly restored the uterus and brought out the pituitary effect. The timer marks minutes and also indicates the base line.

110. The patient vomited everything and at times the vomitus was blood stained. She had gone past the stage of cooperation and there was nothing to do but to abort her. Under ethylene anesthesia the cervix was dilated with a Goodell's dilator sufficiently to introduce a uterine bougie. Patient had good pains for thirty-six hours until she expelled the bougie. The pains then stopped. The patient was given one quarter gr. morphine and a number 3 Voorhees bag was slipped in the cervix. The bag was inflated with lysol solution and the stem of the bag was connected with a mercury manometer so as to obtain a hysterogram. The patient was pretty well exhausted from the previous pains and under the influence of the morphine she slept most of the time the record was being made. She showed no evidence of any pain and when questioned, she said her back hurt a little. You can readily see that the uterus contracted slightly at regular intervals. Eight minutes after five minims of pituitrin were given the uterus went into an incomplete tetanus, typical in character but not violent enough to disturb the patient. Eighty-seven minutes afterwards the pituitrin was repeated. The uterus started to respond as before, but was exhausted. A proctoclysis with five per cent. glucose solution was started at the point indicated and quickly restored the uterus and brought out the pituitary action. The remarkable thing is the rapidity with which the uterus was restored.

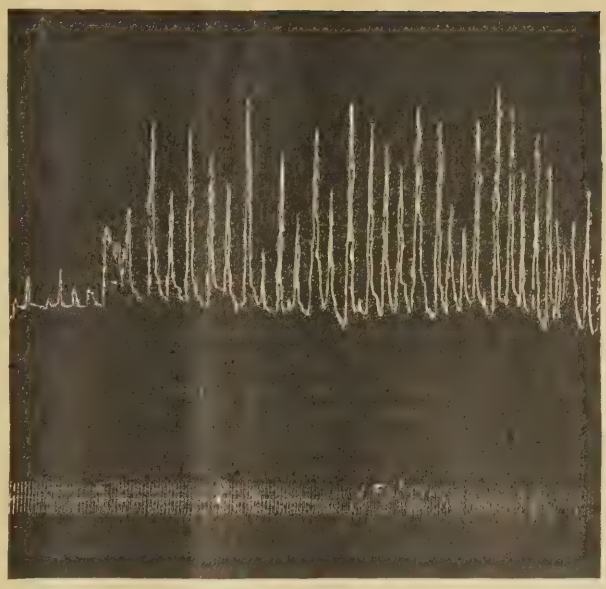

Fig. 2.—Hysterogram of patient at term. This patient had been given ¼ gr. morphine and 1/100 gr. hyoscin before the bag was placed. At a point near the left border a proctoclysis with a five per cent. glucose solution was started. While the contractions increased in strength and somewhat in rapidity there is a period of rest between each pain so that the intrauterine pressure between contractions is unchanged. The timer marks minutes, as well as the base line.

The Importance of the Previous Labors in the Obstetrical History

MEYER ROSENSOHN, M.D.

New York

There are few instances in medicine where the previous history of the patient has no bearing on the complaint. Always of significance, however, except in the acute accidents of practice, the experiences of the former labors in obstetrics are of tremendous value in the decision of the outcome of subsequent confinements. This paper is written because we are constantly seeing cases at the Lying-in Hospital where such factors are decisive, and where disregard of them has led to fetal or neonatal death. There are qutie obviously two aspects of the subject, namely: first, where the previous labor has been abnormal, and secondly, where the previous labor has been normal.

Consideration of the first of these problems is the simpler. Here, a multipara gives a history of labor terminated by an instrumental delivery; or, a prolonged travail, with either a resulting stillbirth, or a baby in whom some serious injury has occurred. This should, if properly analyzed, indicate a disproportion between the baby and the mother, and in the presence of a normal sized fetus, quite naturally, a contracted pelvis of some type.

Such a history when repeated in several pregnancies should render this diagnosis positive and make the attendant take heed of abnormalities. It is not too much to say that with the history of repeated stillbirths and prolonged labor, a Cæsarean operation is justifiable, even though no contraction of the pelvis be made out. The history when indicative of the successful instrumental termination of the delivery by the natural passages, is of great influence in the present labor; one can then assume that the present birth may be accomplished in the same way. Although unfortunately, this is not always true, there is no other criterion that can be used except in the presence of an oversize or overterm fetus, where that can be recognized.

The following three cases taken at random from a number of such occurring constantly at the hospital will serve to illustrate these points.

Case I.—Para iii, generally contracted flat pelvis with diagonal conjugate of nine cm. and a true conjugate of 7.5 cm. When first seen patient was advised of the probability of Cæsarean section. Delivery was made by internal podalic version. The second pregnancy was terminated by a high forceps. The third and last was a spontaneous delivery.

Case II.—Para iii, with a flat pelvis with a diagonal conjugate nine cm. and a true conjugate 7.5 cm. The first delivery was a stillbirth spontaneously born; the second was a high forceps delivery. The third and present was complicated by a polyhydraminos with about six quarts of fluid, which was thought to be the factor in delaying engagement. The delivery was successfully accomplished by an internal podalic version of a nine pound baby.

On the other hand, as illustrating the unfortunate outcome which can occur, the third case will demonstrate the question of judgment or lack of it.

Case III.—Para iii, with a flat pelvis, and a diagonal conjugate of 9.5 cm. and a true conjugate of 7.5 cm. The two previous labors had been terminated by the vaginal route; it was felt that such an outcome would be the case now. An internal podalic version was done and it was necessary to perforate the aftercoming head to complete the delivery.

The other aspect of the problem is a much more difficult one. Here, we have a multipara in whom the history is of labors terminated spontaneously. With the present labor there is apparently some difficulty; if a vertex presentation, there is nonengagement, or there is some abnormal presentation. One does not feel justified in advocating a Cæsarean section in such cases and yet not infrequently a forceps is attempted or a version is done only to get a stillbirth or a baby badly injured. Such cases do occur, and after the delivery has been accomplished the obstetrician feels that interference by the abdominal route would have been less traumatizing to the mother and infinitely more gentle to the baby. These are the hardest cases to decide, and yet, in a measure, we can be guided by certain factors in reaching a conclusion as to the method of delivery. If nonengagement occurs in a multipara with active contractions where there is no pendulous abdomen and the membranes are ruptured some abnormality on the part of the fetus should be suspected. If it can be decided there is no hydrocephalus, or fetal monstrosity, then it is fair to assume a large or nonmoldable head. Then, the question will be one of version, high forceps or Cæsarean; the greatest discernment in deciding which one of these three to resort to will never give one hundred per cent. of good results, but it should be our effort to approach this. Of course, consideration must be given in the decision to the dangers of each of the procedures, both to the mother and to the baby. With proper precautions, even the Cæsarean in an elderly multipara will have its indication.

SUMMARY

1. The history of the previous labors is of importance in the obstetrical case.

2. Repeated stillbirths with prolonged labor should warrant the consideration of Cæsarean section.

3. Repeated deliveries by the natural passages will warrant the assumption, usually, of subsequent deliveries by the same route.

4. Occasionally, a patient with a history of previous deliveries by the natural passages will, because of a large baby, require Cæsarean section.

20 West Fiftieth Street.

The Toxemias of Pregnancy from Their Clinical and Chemical Aspects.—A. Louise McIlroy and E. Pilman Williams, in a paper read at a meeting of the Obstetrical and Gynecological Congress, London, in April, 1925, present a summary of researches regarding the toxemias of pregnancy covering a period of over three years and including the clinical and chemical examination of 172 cases. In order to complete the research seventy cases of normal pregnancy were also examined and used as controls. Also the blood and urine analyses were made in sixty additional cases of labor.

The researches show the advantages of antenatal work, and the authors make the statement that toxemia in many instances is caused by conditions which can be prevented and which have been present previous to the onset of pregnancy. The chief source is intestinal stasis. The unhealthy condition is intensified by the addition of the ovum with its toxins and the additional strain upon the excretory organs.

The classification of toxemias under a dominant symptom or group of symptoms has its disadvantages. The main point is the degree of severity of the toxemia. The clinical findings are identical in the majority of cases whatever the symptoms may be. The terms preeclampsia and eclampsia are merely used to designate the severer forms of toxemia in pregnancy. The authors plead for a broader view of the subject with less symptomatic classification.

From the chemical examinations carried out by Dr. E. P. Williams very little differentiation can be made between the various types of toxemia, but it is possible to distinguish these cases from those of nephritis. This is of value from the point of view of prognosis, as it helps the physician to come to a decision as to the desirability of interrupting the pregnancy. In serious nephritis it is advisable to allow the pregnancy to proceed and save the child if possible. A subsequent pregnancy should be avoided. In a toxic case the wellbeing of the mother should receive the first consideration in view of the fact that even if abortion were induced she would probably have a future normal pregnancy.

Quantitative urinary values have been of little help except in cases of persistent vomiting when high diastatic values were found. These were not found in any of the cases of high blood pressure.

In 172 cases of toxemia chemically investigated and treated, only one patient developed eclampsia, and the diagnosis in this case was doubtful, as the symptoms recurred in two subsequent pregnancies. There was only one death and that from cerebral hemorrhage in a patient with high blood pressure.

The authors do not advocate the induction of abortion unless all other methods of treatment fail. Induction of abortion was performed in only three cases of toxemia, one for pyelitis where one kidney had previously been removed, one for placenta prævia and one for novarsenobillon poisoning. The treatment of the severer types of toxemia is rest in bed and isolation from home affairs. Fresh air, very restricted diet and plenty of water. Colon lavage is of value. Drugs are seldom required. Elaborate charts were prepared showing the urea and nonprotein nitrogen content of the blood in the various conditions of toxemia.

Historical Medicine

The Origin and Early Rise of Pharmacy

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland.

Like medicine and other sciences, the origin of pharmacy was in Egypt, and from here becoming expanded into other countries, it underwent successive changes and improvements which, in the distant past, can be noted in the evolution of all branches of science. Regardless of the use of drugs devoid of any therapeutic action or studied without any method, in spite of the very gross formularies, the details of which frequently escape our understanding, likewise the superstition and intervention of the supernatural which in those days only too commonly formed the basis of the medical sciences, the ancient Egyptians unquestionably made great strides in the progress of the healing art and that of pharmacy. In these matters their knowledge was far in advance of their neighbors, their contemporaries, or even that of the peoples of the Occident in the fourteenth century. Their notions in respect to the properties and the manipulations of medicaments were the result of very judicious observation.

It should be noted that at this early period pharmacy constituted a branch of medicine, and was an inseparable corollary. Some physicians gave themselves up to its especial study, attempting to develop it and render it independent. With the advent of Islamic medicine, the learned of the time studied the new properties acquired by the combination of various bodies, but superstition and love of the marvellous resulted in the creation of alchemy, from which modern chemistry was to be born with the arrival of Lavoisier.

The unearthing of several medical papyri has resulted in throwing much light on our subject. From these ancient writings it would seem that Egyptian medicine has a divine origin. Thot—the Hermes Trismegistos of the Greeks—may share with the healing god I-em-Hetep the title of Egyptian Asklepios. The time when Thot lived is conjectural but it is supposed that I-em-Hetep flourished in 3500 B. C.

To Thot is due the composition of the oldest book which was incorporated in the Hermetic collection. This collection, according to Clement of Alexandria, formed a sort of official and religious encyclopedia, composed of forty-two volumes or chapters, the last six of which comprised the medical sciences. They bore the following titles: 1, *The Constitution of the Human Body;* 2, *On Diseases;* 3, *On the Organs;* 4, *On Medicaments;* 5, *On Diseases of the Eye;* 6, *On Diseases of Women.*

Next to the deities, it is supposed that the Pharaohs of the early dynasties gave themselves up to the study of medicine. Teti, son of Menes, has been regarded as the author of a work on anatomy, while Tosorthos, a king of the third dynasty, contributed a textbook on medicine.

And lastly, the physician-pharmacists belonged to the class of priests and were divided into several categories of practitioners. The *pastophore,* whose social status is not quite clear; the *physician* in the strict sense of the term, who had graduated from a sacerdotal school; the *priests of the Goddess Sekhet,* who, according to Maspéro, were merely bonesetters; and lastly, *the exorcists,* who treated disease by magic words, charms and amulets. Besides these practitioners who cared for disease in general, there existed popular physicians—charlatans or empirical practitioners—such as we have today and which will persist forever. Among these ancient empirics, some treated hemorrhoids, others fractures, and so on. The physician-pharmacist, strictly speaking, is called *sonoro* in Egyptian, *colim* in the Copt tongue, and in Arabian *saïm,* which signifies "preserver," that is to say, he who preserves the body against all diseases.

The *Ebers Papyrus* mentions six formulæ prepared by the following deities: Ra, Show, *Tefrout,* Seb, Nout and Isis. Ra prepared the following ointment for himself:

Honey cooked on the fire	equal parts
Wax	
Chips of the turpentine tree	
Linseed	
Onion	
Cooked raisins	
Cypress seeds	
Castor oil plant seeds (?)	
Lettuce	
Poppy	
Turpentine resin	
Coriander seeds	
Chips of juniper tree	
Fresh sage	

Mix and apply over all diseased parts, against sacred diseases, all lethal diseases and in all kinds of swelling wherever situated.

Here is the receipt composed by Isis for Ra himself, and is sovereign against all ills of the head:

Coriander seeds	equal parts
Poppy seeds	
Sunflower seeds	
Juniper	
Honey	

First mix all the ingredients together, then mix them with the honey and apply.

The remaining thirty-six volumes of the Hermetic Collection comprised the entire Egyptian philosophy and only the priesthood was initiated into the mysteries contained therein, while the practice of medicine was in the hands of the high and low castes of priests. The high caste cured by exorcisms and with the help of demons; they frequently reinforced the effect of the medication by conjuration of the thirty-six demons and by the influence of the stars. The remedies were prepared and compounded by the lower caste priests, who were held in lesser esteem than the high class charlatans.

The medicaments were frequently designated by symbolic names. Thus, ivy was called "the plant of Osiris;" virvain, "the tear of Isis;" a species of

mugwort was known as "the heart of Bubastis," etc. All these names were retained by the alchemists of the Middle Ages, who were wont to surround their doings with an air of mystery. According to Diadorus Siculus, the pastophores were compelled to submit themselves to the written laws; as to the secondary priests they were, according to the same writer, in possession of extensive pharmaceutical knowledge.

The first Greek communications concerning Egyptian pharmacy date from the year 650 B. C., under the reign of Psammetic, hence several thousand years after the beginning, or even the apogee of Egyptian civilization. It was only after the colonization of Lower Egypt that relations with other peoples began, first of all with the Phoenicians. In the *Ebers Papyrus* it is stated that Khoui or Xin, the priest of Râ, was pharmacist in the city of Heliopolis and that he had compounded a special ointment for the eyes. The formula is given but it may be omitted here. This clearly shows that at Heliopolis at least, priest-pharmacists prepared compound medicaments to which they gave their name. Therefore the origin of pharmaceutical specialties may be said to date from this remote epoch of the world's history.

As the practice of pharmacy was carried on by the priests whose dignity was hereditary, it was in their interest to keep their work secret and to make it as difficult as possible for foreigners to have access to their knowledge. Although Haeser supposes that pharmacy and medicine were taught in special schools, I would point out that Diodorus Siculus tells us that not only the lower caste priests practised both medicine and pharmacy, but that there were also learned civilians paid by the state who gratuitously treated travellers and injured warriors.

The aptitude and science of the profession is not only made evident by the complicated preparation of incenses, but in the embalming of bodies as well.

The Berlin *Papyrus* is much like the Ebers. Both documents mention over 700 drugs, but there are few of them which one can identify with certainty. The best known and the most employed are the following: Milk (*artet*) of women, goats, asses and cows; urine (*muit fatit*) of men and women; the excrements (*sau*) of dogs, lions, crocodiles; bile (*as*) of the ox; brain (*udd*) of man; fat (*mereth*) and blood of various animals. Use was made of birds, beetles, turtles and lizards, without forgetting the honey of wild and tame bees. The salt (*hemat*) obtained near Memphis by evaporation of the water was held in high esteem for both internal and external affections. Potassium nitrate was well known, and as it was often adulterated with lime, its quality was estimated according to its taste and solubility.

Both the Ebers and the Berlin *Papyrus* refer to the clay of the Nile, lapis lazuli, sulphur and its metallic compounds, ammonia obtained by burning camels' excrement, etc. The use of metals and their salts was not general, these documents referring only to copper, aluminium and antimony.

Drugs derived from the vegetable kingdom were especially used, but as I have already remarked, few of them have been identified with any degree of certainty. As a matter of curiosity a few that have been clearly identified, may be given here; acorns (*augt*), myrrh (*ausi*), pistacia terebinthus and lentiscus (*aru*), cuminum (*kesnen*), mandrake (*netem*), linum (*sara*), alium sepa and sativum (*uters*), cucumis melo (*sept*), plantago (*afouth*), sage (*anufi*), mint (*tis*), ruta (*eprintu*). Castor oil, conium, Indian hemp and various solanaceæ were known and used. It may also be supposed that the Egyptians were tributaries to India for a large number of drugs, especially aromatics.

That part of pharmacy which today we call galenical, was very complicated in ancient Egypt. Medicaments were exhibited in the form of potions (*necht*), decoctions and mixtures (*abecht*), pills (*pait*), powders (*heit*), boluses (*snat*), etc. For external use there were ointments and poultices (*ana* or *nechem*), plasters (*uret*), collyriums (*stem*), suppositories (*suat*), etc. The sacred numbers, seven and nine, were preferably employed for the weight and number of drugs entering into the composition of their pharmaceutical preparations.

From the formulæ which have come down to us it is evident that their prescriptions were written in a very vague manner, often without indicating the weights and measures or the technic of the preparation.

At the time of the Ptolemies, pharmaceutical science had made vast strides forward and became separated from medicine. Those who practised this art were called Rhizotomes. Manthias, the teacher of Heracleides of Tarentum, was celebrated in these days and has left a description of the more active medicaments in use at the time. Zenon of Tangara made pharmacy a special science. He invented many compound remedies, one of which called *diasticon* was especially prescribed in colic. Next in order came the learned men of the famous school of Alexandria, among them Appollonios Mus (30 B. C.), who wrote a book on the effects of drugs, especially of those he called *euphorista* and *antidota*. Andreas of Carystos is another celebrated personage. Among other things he recognized the adulteration of opium and composed several ointments for ocular affections.

With Heracleides of Tarentum, the preparation and study of the effects of drugs attained a high degree of perfection, and he likewise purged the then existing pharmacopœia of many worthless medications. In his writings he deals with the preparation and composition of medicaments, poisons and their antidotes. He was familiar with conium, opium and hyoscyamus, as well as certain drugs of India, and he says that there is no medicament that he has not personally tried.

Following these brilliant periods came a time of retrogression. The Christians of the early centuries were forced to neglect the medical sciences, obliged as they continually were to combat impious doctrines and to extend their own. As to the Copt monks, they collected the doctrines and writings pertaining to these sciences which they jealously preserved in their libraries, but they made no attempt to develop them further. On the contrary, they rather mutilated them by mixing ideas of superstition and Christianity with them, hence they were the guardians, but not continuers of ancient Egyptian knowledge. The further development of pharmacy was undertaken by the Islamic physicians, but before considering their work

in this direction, something must be said of the practice of pharmacy at Rome.

It must be pointed out that a scientific revolution began with Hippocrates; the writings of this great physician and those contained in the Hippocratic Collection really are the foundation of pharmacy, because the manner of preparing and the forms of medicaments employed today are copied from the procedures of the physician of Cos. The successors of this illustrious practitioner extended his doctrines; it is sufficient to recall what botany and zoology owe to Theophrastos (370-285 B. C.) and Aristotle (384-322 B. C.).

Then the empiricist sect appeared upon the scene and developed polypharmacy, the abuse of which went to extremes. Their doctrine was that since a given medicament is capable of succeeding in a simple case, two drugs combined will act more potently in an affection occupying two sites in the body, while a disease offering several distinct symptoms should be treated by several drugs each capable of acting upon each symptom, hence possessing complete efficiency. The principal representatives of this sect were Nicander of Colophon (185-135 B. C.), who composed two Greek poems relating to the action of animal poisons, and Andromachos, physician in ordinary to Nero and said to be the first Archiater. He composed the famous composition called *Theriaca,* which contained about 150 ingredients, which for centuries to come was to be regarded as the universal panacea. I would point out, however, that Theriaca was merely an imitation of the celebrated electuary of Mithridates, King of Pontus, the first inventor of compound antidotes.

Thus Italy derived medical science from captive Greece, because the arrival at Rome of Greek physicians, either as slaves or free men, resulted in the foundation of Roman medicine and pharmacy. The practice of these two arts was completely free, no previous study or examinations being required. Students followed the lectures of some preferred master with whom thew visited the sick and prepared medicines under his guidance. Briefly put, the teaching was purely practical and clinical. Some of the teaching must have been excellent, when one recalls such men as Dioscorides of Anzaba (40-90 A. D.), Pliny and Galen (130-200 A. D.).

Up to this period pharmacy, medicine and surgery had been combined in one profession by the Greeks. Some historians suppose that medicine became divided into three branches by the School of Alexandria, namely dietetics, or the art of curing disease by diet; surgery, or the art of healing by the hand, and *pharmaceutics,* or the art of healing by medicaments. However, this distinction was never well marked and even appears to have had a short lived existence, because at Rome it became effaced and only traces of it are to be found in the reign of Augustus. At this period some medical practitioners renounced compounding pharmaceutical preparations, leaving this to the care of others.

Women practised both medicine and pharmacy at Rome, where they enjoyed greater consideration than in Greece. They were mostly privileged slaves, superior by the nature of their functions to other slaves of the *familia,* as the following inscription, unearthed in 1825, shows: *"Metilia dona medica."* Truth compels us to admit that these lady doctors often took advantage of their knowledge of toxicology and impunity was frequently acquired, thanks to their profound knowledge of the science of poisons and their antidotes, for they could render either good or detestable services in a time when imperial corruption was rampant and poisonings frequent.

Thus was it that the slave Locusta received liberty and considerable riches as the price for the murder of Britannicus. Other practitioners, less dangerous, for example Pamphile and Meroë, manufactured beneficent love potions potent inasmuch as they put to sleep human pain, or marvellous ointments which could operate improbable metamorphoses, but which, it would seem, did not all have the same virtues. It is said that a young Roman, having heard that Pamphile could change herself into a bird, stole into her laboratory during her absence to abstract some one of her ointments, but unfortunately he mistook the pot and with the first application of the contents he was transformed into a beast of burden. The charm was broken only because he happily was able to graze upon some roses that by chance he came upon.

Pliny, who gave himself up to special study of plants possessing special magical virtues, states that roses when chewed conjured charms.

These simple beliefs would be interesting to study more in detail, although modern science has demonstrated the powerful hallucinating action of certain solanaceæ, such as nightshade, henbane, etc., the ingestion of which disturbs the mental functions to such an extent as to make the *charmed* person believe that he has been transformed into a beast. These remarks are made simply to show to what a high degree the pharmaceutical art and science of toxicology had attained in those remote days.

Pharmacy, which up to this period, had been enriched with more or less incongruous preparations in which all the ingredients of materia medica seem to have been combined, was soon to fall into the hands of mercenaries. The shops of the *pharmacopolæ* replaced those of the old masters and these merchants, abusing the credulity of the public, cynically deceived the people in respect of the quality and quantity of their products, just as occurs today. For this reason the sale of drugs was placed under the care of a governor; they were packed in packages upon which the name of the drug and the place of origin were inscribed and they were then deposited in the imperial storehouses and from these were delivered directly to merchants. Regardless of these precautions the avidity and rapacity of those who gave themselves up to medicinal medicine only increased and it may well be conjectured what might have become of this art in these indigenous hands, had not a new science appeared to inject new life into this decadent pharmacy. This reviving power was chemistry which was to be developed by Islamic physicians of whom we shall now speak.

The Islamic physicians gave a new impetus to the study of medicine and pharmacy. They compounded their own pharmaceutical preparations for use in their practice and for this reason pharmacy was not a distinct profession with them. There did exist a class of herborists who sold dried plants and

drugs directly to the public, but they did not prepare medicines, although they did sell all kinds of poisonous substances.

Among the learned Arabian physicians, some cultivated the study of pharmacy and with great success. It was they who invented the names of alcohol (*el-kohl*), syrup (*sharab*), camphor (*caphour*), opium (*afioun*), ether (*eter*), etc. At the time of the Caliphs the medical profession had composed a kind of pharmaceutical codex containing medicinal preparations sanctioned by the government, the compounding and sale of which were controlled by proper authorities. The most complet codex was published towards the end of the ninth century under the title of *Akrabas* or *Krabasines*. Another treatise on pharmacology appeared in the twelfth century, written by Abou-el-Hassan-Abdallah-ibu-Tamine, the ulema and physician to the Caliph of Baghdad. This work acquired great celebrity and was used as a guide in the preparation of compound medicaments. Authorized under the seal of the Caliphs as a Codex of Pharmacy this treatise also laid down the prices of each preparation.

Avenzoar, a physician and surgeon of the eleventh century, was particularly distinguished in the art of pharmacy. He invented a number of syrups, tinctures, elixirs and electuaries and his treatise clearly shows that he must have dipped deeply into the study of various drugs in order to discover their active principles and to extract them.

The Islamic physicians also made known several drugs derived from India, China and Persia, as well as from Central Africa, such as camphor, various gums and resins, and a large number of plants, roots, barks, etc.

At the time of the Caliphs a decided taste for alchemy was rampant and this science was applied to the manufacture of glass, dyes, enamels and to metallurgy. In Gerber's famous work which dates from the eighth century, there is question of corrosive sublimate, red precipitate, nitric acid and a number of other chemicals. At a later date, a number of Arabian writers—mostly physicians (*tabib*)—applied alchemy to pharmacy and therapeutics. Rhazes in his books, refers to borax, orpiment, realgar and the use of alcohol as an excipient and dissolvent of various pharmaceutical preparations. He also studied various compounds in which sulphur, iron, copper entered, as well as preparations having arsenic, mercury, antimony and zinc as bases.

The treatise on materia medica by Aben-Gulfith-el-Haoui gives an excellent idea of what medicine derived from the chemical operations outlined by Rhazes in his book.

After the twelfth century the Arabs ceased to progress; they even retrogressed in the sciences and arts that they had created and gradually returned to their primitive state. Finally their ignorance was such that even among the class of ulemas reading and writing were unknown.

After the decadence of Arabian culture, the progress in the art of pharmacy remained at a standstill until the year 1546, when the first edition of the *Dispensatorium* of Valerius Cordus was published, which was the foundation stone upon which modern pharmacy was to be built.

The Brave Soldier: An Operation for the Removal of a Fatty Tumor in the Year 1665

SIR D'ARCY POWER, K.B.E.
London

Many accounts of amputations are extant but few details of operations for the removal of tumors, other than cancer of the breast, have come down to us from bygone ages. Haller, however, has preserved one in his great collection of *Surgical Theses*. It was recorded by Joan Sigismund Elsholz, of Berlin, on January 9, 1666, in the following words:

"Michael Nebel, a Captain in the foot guards (*decurio de legione praetoriana pedestri*) of his serene highness our Elector, consulted me in the autumn of the year 1665. He said that six years ago he noticed a lump, no bigger than a pea, near the perinaeum on the border of the nates close to the anus.

"He had not taken advice because it caused no pain or trouble but it had increased in size until it extended to the front of the left groin. It had become so big in the course of the last month that the skin had first stretched and then given way and during the last few days it had grown still more rapidly. The patient, who was thirty-seven years of age, tall, thin and healthy, said further that the only inconvenience the swelling had caused him was formerly when he was a dragoon and had to ride, and he dated the beginning of the swelling from that time.

"The swelling felt hard and was so resilient on pressure that it seemed at first sight to be a sarcoma or fleshy tumor. He was advised to have it removed piecemeal as it might suppurate, but as he did not agree to this it was decided to remove it at one sitting. The operation was fixed for December 6th and the patient was ordered to be purged and bled in preparation for it. About eight o'clock in the morning Dr. Martin Weise junior and I as the physicians, with two surgeons were in attendance and when everything was ready the patient was laid upon the operating table (*scamnum*). He declined to be tied down as he thought it was unbecoming for a soldier, but nevertheless we had two lusty men who held his arms and legs. The tumor was first wrapped in lint on account of its slipperiness and its base was transfixed with a needle and thread from one side and then with a second needle and thread from the other side. The ligatures were tied tightly in case there might be severe bleeding. The whole mass was then cut away quickly with a sharp knife, and a dressing

soaked in white of egg and bole was applied at once to the wound. The leg was then bandaged and for greater security a bandage was put round the belly, and the patient who had borne the operation manfully (*et aegrotus qui mascule sectionem pertulerat*) was put back to bed.

"Twenty-four hours later the tighter bandages were removed and the others were loosened but the styptic dressing was left untouched. Appropriate remedies were given from time to time and the wound healed in a month.

"Examination of the tumor showed that it weighed two pounds and that it was shaped somewhat like a pouch for it was rather narrower at the base and at the apex. It was found on section to consist of a fatty substance so like fresh lard in color and consistence as to be indistinguishable. It had a covering membrane about as thick as a straw and thin membranes were distributed throughout the whole fatty mass in such a way as to divide it into lobules (*in cellulas*)."

There are several points of interest in this short account. In the first place, there is the brevity of the note which expresses the facts in such clear language that the exact nature of the case can be understood after the interval of two hundred and sixty years since it was written. Then there is the courage of the patient who decided that whatever had to be done should be done all at once and not piecemeal as his somewhat timid surgeons recommended, while he saved his professional honor by refusing to be tied up for "it was not becoming in a soldier to be bound."

The professional relation in which the surgeons stood to the physicians is also brought out for the two surgeons were clearly acting under the authority of the physicians. It will be remembered that at the same period in England it was ordered that "no surgeon be so bold as to trepan, or open the belly except in the presence and on the advice of a physician." In this instance the surgeons were dreading the loss of blood which might occur, no vain fear when the only means of arresting hemorrhage was by the application of styptics for there were no pressure forceps and the tenaculum for picking up the bleeding points had hardly come into use. Lastly, there is the careful examination of the tumor after removal which shows that it was an encapsuled lipoma. Appended to the report is a full page illustration.

Contributors to Medical Science

Hermann Boerhaave

Some three or four hundred years ago Holland was renowned not only for commercial supremacy but for the culture and learning of her citizens and the high position they took in art and science. Leyden was one of the most famous universities of the world, to which students from other countries flocked, as somewhat earlier they flocked to the Italian universities. Of all the graduates of Leyden few gained greater fame than Hermann Boerhaave, one of the most celebrated physicians of the eighteenth century.

Boerhaave was born in the village of Voorhout near Leyden on December 31, 1668. His father was a clergyman and a learned man, and his only son Hermann was destined for the Church and educated accordingly. At the age of fourteen he was sent to the public school at Leyden, where he showed remarkable ability, and at sixteen was admitted into the university. He studied under the best teachers of the day, logic, natural philosophy, metaphysics, ethics, rhetoric, chronology, geography, mathematics, Hebrew and Chaldee. He already knew Latin and Greek.

When twenty-one years of age, he delivered an academic oration and in 1690 he took a degree in philosophy. Hitherto his views had been directed to divinity but he was advised to join the study of physic to theology. So much did he like the study of medicine and so apt was he in acquiring knowledge therein, that he resolved to take a degree in physic before his ordination. He studied anatomy with great zeal but paid most attention to the works of Hippocrates because he found, from a perusal of the Greek medical authors, that after the "Father of Medicine" little novelty to be found. However, he did not wholly eschew the modern medical authors, in particular he esteemed the works of Sydenham. He made himself conversant with chemistry and botany and then went to the University of Harderwick, in Guelderland, where, in July, 1698, he took the degree of doctor in physic. At this time the union of medicine and priesthood was not common.

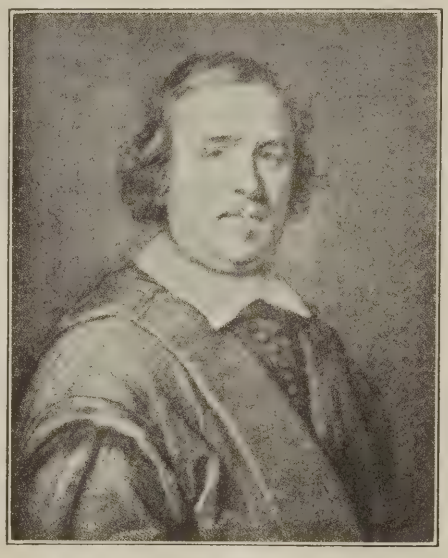
In old Egypt the union of physic and priesthood was a matter of course and up to the time of Hippocrates the practice of medicine was almost entirely engrossed by the priests. It was Hippocrates who first detached medicine from theology, or rather superstition, and raised it to a science. But this divorce was not lasting. In the twelfth century, under Pope Calistus II., the first Lateran Council, held in 1123, peremptorily forbade the interference of the clergy with the sick in any other way than as ministers of religion. The Council of Rheims in 1131 emphasized this ruling. These ordinances had so little effect that in the second Lateran Council in 1139, monks and canons were threatened with severe penalties for neglecting their religious duties, and applying to medicine as a means for "obtaining ungodly lucre."

As a matter of fact in later times, throughout Europe, and in France in particular, the duties of the physician were performed chiefly by ecclesiastics. In those times clerks and monks were the only members of the community given to study, and somewhat naturally they alone were deemed capable of

treating diseases. It will be remembered that the immortal Rabelais was both monk and physician, while among abbés, canons, bishops and so on, who filled this dual position to their rulers and patrons, may be enumerated, Fulbert, Bishop of Chartres; Lombard, Bishop of Paris; Roger of Provence, physician to Louis VIII.; Robert Donay, a prebendary and physician to Margaret of Provence; Oblizo, abbot of St. Victor, physician to Louis the Big; Rigord, a monk of St. Denis, and author of Philip Augustus.

Cabanis contended that the medical and priestly professions had many features of resemblance, that both brought into action the same motive principles, hope and fear, that medicine, like superstition, unquestionably exerted on the minds of men an influence in proportion to their weakness, and as the former acted upon more real and palpable objects than the latter, it followed that the most rational and enlightened men could never resist its power.

After this digression to return to Boerhaave. Subsequent to taking the degree of doctor of physic at first his practice was very limited, but in 1701, by the interest of friends, he commenced a series of lectures on the institutes of physic and so successful were these that he was requested to teach chemistry in addition. About this time he appears to have first publicly argued for the use of mechanical reasoning in physic.



HERMANN BOERHAAVE
(From Garrison's *History of Medicine*)

Boerhaave, however, not only endeavored to explain the functions of the body in health, the phenomena of disease, their causes, symptoms, and even the action of medicines for their relief, according to laws of statics and hydraulics, but also by the operations of chemistry. And in this direction it may be said that Boerhaave displayed his originality of mind and perhaps his foresight, as it is believed by many now that in a thorough and correct understanding of biochemistry is to be found a solution of the cause of disease and that in the practical application of that knowledge is to be found the conquest of disease.

In 1709, Boerhaave succeeded to the chair of medicine and botany in the University of Leyden, and attempted to fix the science of medicine upon the basis of observation, experiment, and the inferences naturally deducible from such a method. His zest for the study of botany, manifested in the addition of plants connected with medicine, rendered it necessary to extend the botanical gardens of Leyden to twice their original dimensions; and such was the esteem felt for him and admiration for his labors that in 1714 he was placed at the head of the University, by receiving the appointment of Rector. In this year, too, he became professor of the practice of physic. He was further elected president of the Chirurgical College, at this period medicine and surgery being regarded as being indivisible.

In 1725 the Royal Academy of Sciences of Paris elected him into their body, and in 1730 he was admitted into the Royal Society of London. In 1737, he was attacked with difficulty in breathing; he had suffered from gout for many years, and described his disease in a letter addressed to Baron Bassand, physician to the Grand Duke of Etruria. He gave an account also of his case more in detail to Dr. Mortimer, secretary of the Royal Society; and speaks of his immoderate fatness, brought about by his inability to take exercise. He described all the symptoms of hydrothorax from which he died on September 23, 1738, being then nearly seventy years of age.

Boerhaave had a very extensive practice, being consulted by all sorts and conditions of people. All the distinguished persons who passed through Leyden visited him and the Czar Peter is reported to have lain all night in his pleasure barge, against Boerhaave's house so as to have the opportunity to converse with him for two hours on various points of learning the following morning before college time. Students from all quarters of the civilized globe came in large numbers to attend his lectures. He married at the age of forty-two and left to his only surviving daughter a fortune of two millions of florins. His library was sold by auction. It was rich in the best works of medical authors, and also in other departments of learning.

Boerhaave wrote several works, the best known of which was one in support of Malphigi on the structure of the glands, indeed the sweat glands are now known by the name of Boerhaave's glands. Another well known work was the *Elements of Chemistry*, an altogether excellent production and far in advance of any book on chemistry published previously. Boerhaave was a great botanist and, perhaps, on the whole shone more in his knowledge of botany than in any other branch of medicine. He wrote two books on botany. The great Swedish naturalist, Linné, admitted that Boerhaave had formed his genera plantarum in the most accurate manner, looking particularly to all the parts of frutification in the arrangement and describing them with a precision such as to render the plates almost unnecessary for illustration.

Boerhaave will go down to posterity as one of the great physicians of the world and may be regarded as a factor in lifting the medical profession out of the slough into which it had fallen. He was scientific, or attempted to be scientific, in an age when medicine was given over to superstitition, and a really learned man when most of the physicians of the time were veneered with superficial knowledge, as depicted in Molière's *Médécin malgré lui* and relied for practice on their ability to humbug the even more ignorant public. In the time of Boer-

haave medicine in Europe was on a more scientific basis than in Great Britain, and the medical profession was more highly esteemed, and men of Boerhaave's stamp were responsible for its advance in all parts of the world and for its present high position.

Hippocrates: a Medicohistorical Note on the Howard A. Kelly Collection.—Dr. John Rathbone Oliver writes (*Bulletin of the Johns Hopkins Hospital*, September, 1925) that the gift of Dr. Kelly to the library of the Johns Hopkins Hospital is an important event in the hospital's history. The collection has not yet been catalogued, but has been arranged in an approximately chronological order, so an idea may be given of its contents. "Inasmuch as my own studies," writes the author, "have for some time past been centered about the Hippocratic Corpus, I can, it seems to me, offer my thanks to Dr. Kelly in no better way than by sketching some of the problems that are connected with the name of Hippocrates and by showing what help in solving them is afforded to a scholar by the books that, thanks to Dr. Kelly, we are able to consult here in Baltimore without being forced to wander far afield to other libraries and collections. . . . Like all collections that have been gathered together during a long period of years, and without any very definite guiding plan, the Kelly Collection is not all on the same level of excellence and completeness. It has its bare spots, just as it has its spots of richness—at times, almost of plethora. After the well filled shelves of Hippocrates, there is a gap between Hippocrates and Galen. One searches in vain for Aretæus, Rufus of Ephesus, and especially for Dioscorides. Later on in the sixth century Aetius and Alexander of Tralles . . . are missing. But these are details. . . ."

Dr. Oliver then sketches the Hippocratic problem by touching on four main topics—the Hippocratic problem itself, the Hippocratic Corpus, or collection of Greek medical books included under that general title, the manuscript tradition on which the oldest printed editions of Hippocrates are based, and, lastly, these editions themselves. The first topic, that of the Hippocratic problem, may be summarized by the statement that of this wonderful personality that dominated medicine from the fourth century B.C. until less than a century ago, we know practically nothing about his life, character or methods of teaching; and of the books bearing his name, there is scarcely one that has not, at one time or another, been rejected by scholars and editors as manifestly unauthentic. To take up, then, the second topic—what is this collection of some sixty medical books that we call the Hippocratic Corpus? "In the first place, it is a very wonderful collection indeed. There is scarcely any domain of modern medicine which it does not touch at some point or other. The surgical books are marvels of accurate observation and technical skill. . . . Manifestly, it is not all the work of one man. Study the books critically and you will see at once that they do not all even represent the teaching of the same school of medical thought. . . . Modern scholars are fairly in accord in believing that our Hippocratic Corpus represents the remains of a medical library, the medical library of the great medical school at Cos." The author goes on to describe the survival of the Hippocratic Books through the conquest of Greece by the Romans, the burning of the Alexandrian library, and during the centuries of the Middle Ages, when the monks were the chief practitioners of medicine. This brings us to the third problem—that of the manuscripts. The four most important of these belong to the tenth and eleventh centuries. These are *Theta*, or *Vindobonensis med. IV*, in Vienna, our oldest codex; *Parisinus 2253* or *A* in the Bibliothèque Nationale in Paris; *Parisinus 446, Supp.* or *C*, also in Paris; and *Laurentianus 74.7* in the Laurentian Library in Florence. Another important manuscript is in the Vatican Library in Rome. The fourth period covers the printed work of Hippocrates, and brings us into touch with the Kelly Collection. Dr. Oliver outlines the history of these printed editions, from the earliest, which appeared in Rome in 1525, through some of the most famous modern editions, and comments upon the eagerness with which all scholars are looking forward to the appearance of the great *Corpus Medicorum Græcorum*, which will contain all the medical writings in Greek of which manuscripts are still extant. This Corpus has been undertaken by the two Academies of Science of Berlin and Copenhagen.

Probably the most popular of the works of Hippocrates was the *Book of Aphorisms*, opening with the famous sentence, *Ars longa, vita brevis est*, translated into every known language and used in some form by almost every poet and dramatist. The Kelly Collection contains whole shelves of editions of Aphorisms. "The most interesting perhaps is the edition of Leonhard Fuchs, Professor at Tubingen (1501-1566). He was suspected of being a Protestant or Lutheran, so in many copies of this edition his name is blocked out in ink, and several sentences in his Preface are scratched out." Next to the Aphorisms in popularity came Prognostic, a book that has been accepted as genuinely Hippocratic. Then the French physician, Duret (1527-1586), published a folio Commentary of "Coan Prenotions," one of the oldest treatises of the Corpus, probably pre-Hippocratic. In the Kelly Collection there are two beautiful copies of this folio.

Dr. Oliver closes his article with the expression of the wish that it may serve as a guide to those interested in the collection, and gives a cordial invitation to all such to climb up to the gallery on which the collection now stands, and to browse around in it, taking down one book after another.

Richard Bright on Medical Ethics.—"Many are the moral questions which will arise to you in your professional life, and for the solution of which you must turn to a strict code of ethics, not printed on the leaves of a book, but engraved upon the tablet of the mind. These questions will refer, not only to your patients, but to you, amongst yourselves, as fellow practitioners." He points out "that it would be no easy matter to enumerate the questions, or write out the code by which they could be answered. But it is satisfactory to know that a cultivated understanding, an upright mind, and a full determination to act on the golden rule . . . will either anticipate and prevent the emergency, or point out our line of duty when it arises."—R. T. Williamson's *English Physicians of the Past*.

Editorial Articles

DEVIL AND DEEP SEA

"There are many ills different from those of repletion, but no less dreadful, arising from deficiency of diet." So said Hippocrates, and so affirms the twentieth century physician. Just where the line between the one condition and the other is to be drawn is something which no one, ancient or modern, can quite say.

Doubtless the Father of Medicine had in mind only the matter of quantity, for in his day foods had not been so denatured and so sublimated as in our own time. There is plenty of evidence that there was deficiency in essentials, or, what may possibly affect the same damage, plethora of nonessentials among the old Greeks.

The matter of minerals and vitamines is uppermost at present, but we have not yet settled about the amount of protein. Chittenden said it should be thirty grams, and Voit, a hundred or so, and there is considerable difference. The former showed laboratory proof, the latter the evidence of common practice, though common practice is seldom the best practice. A certain proportion of fat has been set forth in certain dietaries, but the matter of quantity has never been taken up seriously, that is, laboratory-wise, and we do not know whether we are right in indulging in fifty or in a hundred and fifty grams.

As for starch and sugar, we are as far from exact knowledge, save that we are told we should not become too fat, and starch and sugar make for fat, and yet a certain amount of fat is believed to be desirable, though, as we rarely draw upon it for use, it would seem more as a protection against cold than for any other purpose.

With our more recent acquisition of knowledge of deficiency diseases other than starvation, we are the more piqued to know about the diseases of repletion other than obesity. It has been guessed that chronic rheumatism, rich man's gout, the stone, and forms of neuritis may be due to indiscretions on the side of excess in special foods, and wild and various have been the recommendations to patients regarding their food. On this score the rheumatic is a particularly confused witness. Withal we have doubtless been half at fault in forgetting that an excess of one food, as of sugar, might be the real cause of what we thought was too much of another, as of meat, too much of the former interfering with the handling by the body of what was not too much of the latter.

The whole dietetic atmosphere is full of shapes, but they are seen rather darkly as yet. However, it ought to take some time to dispel the fog of ignorance with regard to this business of eating which has hung over us from far beyond the time of Hippocrates—in fact, from the days of the beginning of cookery and the era when the looks and taste of food were considered paramount.

NEURASTHENIA

Because it cannot be percussed, auscultated or otherwise laid hands on physically, there are not a few clinicians who are of the opinion that a diagnosis of neurasthenia is but an expression of ignorance of the true cause of the condition of the patient exhibiting certain general symptoms. We are too much tied to organic disease and we lose many patients to other cults because we have little patience with the feelings of patients. All feelings of dis-ease are signs of disease, physical or mental. It is fortunate that there are such signs and he is fortunate who gives due consideration to them, even if the person who has lost his ease is still able to be about and shows no perceptible evidence of cellular degeneration.

Dr. Frederic Peterson, in his address as president of the American Neurological Association, has called attention to the reality of this disease, to its frequency and to the fact that the study of its origins has been very much neglected. He states that cases of neurasthenia form at least one third of the clientêle of the neurologist (in his own experience thirty-eight per cent.) and yet the neurological literature on the subject is very meagre indeed.

He calls attention to the results of McCollum's experiments in which all degrees of nervous excitation and evidence of anxiety were brought about in animals by deficiency diets and he is confident that the same cause is often a factor in the production of nervous exhaustion in humans. He is certainly not wrong in saying that "there is good reason to believe that not only all children but all adults suffer from some degree of dietetic error" and we know well enough that many suffer to a very high degree.

He recalls the success of Weir Mitchell with these cases and believes it was the diet of butter and milk and codliver oil, etc., which had as much to do with his success as anything else.

He deplores our diabolic ingenuity in denaturing foods and our silly profligacy in feeding to the hogs the elements most essential to our own welfare, and he goes on to remark that the vast and growing con-

sumption of candy and soda water will shortly need a twentieth century amendment to the constitution on the ground that "in the long run and on a wider scale they are more destructive than alcohol."

In some sickness statistics which have come to the attention of the writer it is interesting to find that neurasthenia is relatively infrequent among industrial workers as compared with clerical workers and teachers. It is evident that those who handle things are less subject to nervous wear and tear than those who come more in contact with people. The industrial worker is also less tied to his job and can more readily tell his employer to go to the other place if he is not well treated. Possibly, also, a more severe use of the eyes adds a final straw to the back of the camel already weakened by deficient diet and by excessive burdens of one sort or another. Among the teachers of Victoria, Australia, the percentage of sick leave due to neurasthenia advanced among men from 10.67 per cent. in 1914 to 16.65 per cent. in 1920, and among women from 15.56 per cent. to 19.20, which is but another illustration of the blessings of war.

The duration of neurasthenia makes it a condition more than "doubly" serious, for whereas the case of influenza or tonsillitis runs a week or ten days, that of nervous prostration lasts a month or more and full recovery is always in doubt.

THE DOCTOR AS A BUTT OF THE SATIRIST

The medical man has ever been the butt of the satirist and it must be said that there was a time when he fully deserved the arrows of satire which were aimed at him.

In the wide times of Elizabeth and a little later when pedants abounded the doctor was conspicuous for the assumption of knowledge which he did not possess, and overawed his patients and at the same time covered his own ignorance by the use of technical and high sounding terms. Ben Jonson satirizing the pedantic fashion of the age sets up the doctor as one of the objects of his shafts. In the *Staple of News* he makes a character, one honest Pennyboy Canter the disguised father, to speak his bitter views on the "canting" prevalent among poets, strategists, astrologers and the rest. His son spurs him on with a challenge, "On to thy proof; whom prove you the next canter? and the poet retorts:

> The doctor here: I will proceed with the learned—
> When he discourseth of dissection,
> On any point of anatomy; that he tells you
> Of vena cava, and of vena porta,
> The meseraics and the mesenterium.
> What does he else but cant?
> Do I despise a learn'd physician
> In calling him the unconscionable Dr. Almanac, "a Quack salver?"

It should be remembered that in the language of the day "anatomy" signified not only a "dissection," on a "dissected body," but also a skeleton of all those who satirized the medical profession in pungent verse or prose none bit deeper or excoriated more painfully than Molière in his immortal *Le Médecin Malgré lui* or Le Sage in *Gil Blas*.

There are, however, not lacking satirists of the profession at the present time. George Bernard Shaw never misses the opportunity of girding at physicians and surgeons. It was the other day only that he flouted the surgeons of England saying that many of them were so devoid of manipulative skill that they did not possess the dexterity to tie their own shoe laces properly. Perhaps it is well that there are satirists of the profession, failings held up to public ridicule are likely to be corrected quickly which is to the advantage of all concerned. But the doctor of the day can assuredly lay the flattering unction to his breast that in knowledge and skill he is a vast improvement on the pedant who flourished in the time of Ben Jonson or of Molière or of Le Sage.

A DISAPPEARING DISEASE

The medical practitioner of the older generation has lived to see the almost complete disappearance of yellow fever. Formerly the summer scourge of the southern states, it is now almost as extinct as the proverbial dodo, in spite of the fact that the insect vector of the disease continues to thrive in many localities in the South. A variety of conditions has served to bring this to pass, chiefly, the attack upon the disease in its residual foci of Central and South America and the change in the type of ships which ply between the United States and the seaports to the South.

It is interesting in this connection to take note of another disease which has disappeared from many parts of the world, although in India and China it still takes a terrific toll of human lives. At one time bubonic plague was the perpetual menace of the British Isles, where there are many records of the disease from A.D. 543 onward. For the three years, 1348-1350, there was an appalling mortality from plague and for the next three hundred years the disease smoldered with occasional epidemic outbreaks. The years 1603, 1625 and 1665 were marked by great plagues in the centres of population, particularly in London. Then came the Great Fire which destroyed practically all of the nonratproof buildings of the city, and when it was to be reerected the rebuilding act of 1666 required that all London houses be built of brick or stone. Since that day plague has ceased to be a practical hazard to the city of London, because in building fireproof buildings its citizens iso-

lated themselves from the houserat and hence from plague of which the rat is the carrier.

In less dramatic fashion, this principle of evicting the rodent from the home of man has been practised and always with beneficial results in the eradication and prevention of bubonic plague. Man has now learned that it is poor economy to erect buildings which are not fire and ratproof and in this age of concrete plague is becoming a rapidly disappearing disease. Of course there are other factors which have assisted. The improved economic condition of the human race and the concomitant desire for the luxury of cleanliness have combined to make man live in better, less flea ridden houses. More and more plague is being restricted to those portions of the world where people live in filth and squalor with the rat and his parasites, and the oncoming generation of medical men will find bubonic plague even a greater curiosity than it is today.

THERAPEUTIC EFFECTS OF LIGHT

Members of the medical profession are likely to be attacked occasionally by fads and obsessions. A drug leaps suddenly into fame, launched into favor by a well known physician, and is employed on a large scale, until its continued use reveals certain countervailing effects or is superseded by a therapeutic agent extolled by another leading light of the profession, when it sinks into comparative oblivion.

During recent years it has been mainly around diet that medical scientific discussion has raged. Not many years ago the caloric content of a diet was regarded as the criterion of its nutritive value and more recently the vitamines have held the field although they are being ousted, to some extent, by the mineral salts and, perhaps, by iodine in particular.

The value of sunlight and the ultraviolet rays are now being recognized as incomparable curative and remedial agents and are acclaimed by many as panaceas for almost all human ills. While it has been shown undoubtedly that the effects of light in the treatment of certain diseases are amazingly beneficial, and while granting that its deprivation from the health point of view is frequently disastrous, it yet appears that its curative and remedial virtues are being somewhat extravagantly exaggerated in some quarters. It has been stated that rickets is due to lack of light and unhygienic housing conditions and environment only and that diet plays no part or a very subsidiary part in its production. It is true that to diet was attributed formerly a too potent influence in bringing about rickets and some other conditions, but the pendulum now seems to be swinging too far in the other direction.

Sunlight is the great natural sterilizer, kills hurtful germs and is the greatest mental stimulant. Ultraviolet rays, in the absence of sunshine, have been employed with extraordinary good effects. But the question remains, has sunlight or the ultraviolet rays the wonderful healing and recuperative powers which have been ascribed to them? In the *Medical Press and Circular,* April 22, 1925, the subject is discussed logically in the editorial columns. It is asked how do the ultraviolet rays produce constitutional effects, such, for instance, as increasing the flow of milk in a mother or benefiting the rickety child? Is it the case, as has been suggested, that sunlight stimulates the formation of vitamine A? But with regard to sunlight, while vegetable organisms cannot produce chlorophyll and build up starch without it, animal organisms do not appear to be directly dependent upon it, at any rate, not upon the direct rays of the sun.

The case of birds and mammals is quoted in support of this argument. In birds the effects of sunlight are excluded with a few rare exceptions by their feathers, and in mammals, excepting only man and the pachyderms, light for the most part is as effectually screened from them by their hairy coat as from birds by their feathers. Moreover, the thick hides of the pachyderms exclude light as completely as the feathers and hairy coats of birds and other mammals.

Man, indeed, is the only naked animal and, perhaps, it is likely that it is because he adapted himself to conditions, and these conditions necessitated no protection as the life led by birds and the other mammals necessitated it. Nakedness in man is no doubt an adaptive feature. But although man is naked, special precautions have been taken to protect his tissues from the action of a powerful sun. Where the rays of the sun fall with extreme actinic power, the skin is marked by pigment, and the thickness of the pigment is in direct proportion to the proximity of the regions they inhabit to the equator, where the sun's rays are most intense. On the other hand, in colder climates, where man is closely encased in clothes, pigmentation is less marked, and in lands where sunshine is scanty, the inhabitants tend to be blond. There is this evidence that man has developed a pigmented skin for the express purpose of shutting out light from the tissues. Therefore it seems as if light is not only not essential for man to live in health, but except in moderate quantities is actually injurious, otherwise why should such careful precautions have been taken to protect his tissues from sunlight.

Again, it is not the people who inhabit those climes in which the sun exerts its power most fiercely who are the most healthy, vigorous and energetic physically and mentally. Long exposure to a climate such as this is enervating both to body and mind.

The race which inhabits the lands where the sun shines but little leads the world in vigor of body and mind. The problem is confusing.

A certain amount of sunlight is essential to health and sunlight and also ultraviolet rays are beneficial in certain diseases and conditions of ill health, but it has yet to be proved how the direct rays of the sun are beneficial to health and why the inhabitants of lands in the torrid zone are inferior physically and mentally to those of the temperate zone. It is difficult to comprehend how and why the ultraviolet rays exert a potent constitutional effect. The editor of the *Medical Press and Circular* puts the situation well when he says that he cannot doubt that the direct beneficial effect of sunshine upon the body is insignificant as compared with the benefits derived from fresh air in the open. No kind of life is so health-giving as life in the open air, it seems to matter little whether the sun shines or not.

INSECTS AND DISEASE

While insects are beneficial in some ways, on the other hand, they exact a large toll in life, in ill health and in damage to agriculture. Insects are the chief pests of tropical countries and one of the main reasons why the tropics are not being utilized more rapidly by the human race in general. Knowledge, however, as to the habits of insects is increasing and with such knowledge will come a more general adoption of preventive measures.

As Dr. E. P. Felt, State Entomologist of New York, points out in the *Scientific Monthly* for December, 1925, it is impossible to believe that under present conditions wholesale decimation may result from insect borne diseases. The black death of the middle ages occurred at a time when the louse was a universal domestic incident and dwelt with royalty and the peasant alike. Plague, which ravaged Europe in the old days and which flourishes still in the Far East, is essentially a disease of dirty environment. When it swept in death dealing epidemics through Europe, sanitary and hygienic conditions prevailed which are unbelievable to the present generation. Plague remains a menace in Asia because the conditions in the overcrowded countries of China and India are, generally speaking, filthy in a high degree.

During the world war the stage was set for tremendous outbreaks of certain epidemic diseases, typhus in particular, but knowing the cause of this disease enabled those responsible for the health of the armies to take effective steps to stop it or to check its course.

Early in the history of this country yellow fever incited terror. Now, on account of the application of known facts of its genesis, it is almost a negligible quantity. Yet it is more or less prevalent in some South American countries where the gospel of cleanliness is not thoroughly carried out.

Malaria is the most conspicuous example of a disease carried by insects, but it is only because money is lacking to provide adequate preventive measures that malaria continues to be such a potent cause of mortality and ill health.

Widespread epidemics of insect borne diseases have ceased to menace mankind, because medical men have learned that insects without the infection are practically harmless. The object aimed at in preventing the spread of diseases carried by insects, is to keep down the number of carriers to a minimum and to safeguard the remainder from infection. It may not be too optimistic to predict that the end of insect borne diseases is in sight.

Obituary.

SIR R. DOUGLAS POWELL, Bt., K.C.V.O.

London

Richard Douglas Powell was born near London on September 25, 1842. He was educated privately and at University College Hospital Medical School. He graduated with the degree of M.B. from London, and received the diploma of M.R.C.S. in 1865 and the degree with honors the following year.

In 1868 he became physician to the Brompton Hospital for Tuberculosis. In 1871 he was appointed assistant physician to Charing Cross Hospital, and in 1874 became full physician at the Brompton Hospital. In or about 1877 he left Charing Cross to become assistant physician to the Middlesex Hospital; in 1882 he became full physician and lecturer on the practice of medicine, and in 1900 on retiring from the active staff he was appointed consulting physician. At a comparatively early age he was appointed to the Court of Queen Victoria. He became a member of the Royal College of Physicians in 1867, a Fellow in 1873, was elected president in 1905, and reelected on four subsequent occasions. With Sir Thomas Barlow he attended Queen Victoria in her last illness. Dr. Powell was an authority on diseases of the lungs and heart and his many contributions to literature as well as two books, one of which ran through several editions dealt with these diseases.

He was the last of that distinguished band of physicians of which Sir William Jenner was the leader. Powell was of slight build, clean shaven and almost ascetic in appearance. He possessed the old world courtesy, was gentle and deliberate in speech and of great personal charm. He was as thorough in his written opinions as in his spoken word, and all the details of treatment were discussed by him most carefully. Sir Richard Douglas Powell was almost the last representative of the consulting physician of the old school, dignified, courteous, and quiet, a complete contrast to many of the new school.

Fig. 1.—Partial view of Baden Baden

Baden-Baden, the Queen of the Black Forest

ELSA DENHAM
New York

"The Garden of Eden of Central Europe," Baden-Baden has been called, and, in fact, in point of natural beauty it need fear no comparison with any other city in Europe.

This exquisite health resort, annually the meeting place of the fashionable élite from all parts of the world, is centrally situated on the main traffic railroad lines—Berlin—Italy—Vienna—Paris—and may be reached directly by express trains from all parts of Europe. One of the oldest resorts known, no one can say to what remote antiquity the origin of Baden-Baden belongs. History tells, and ruins confirm the tale, that Emperor Hadrian built a bath house here eighteen hundred years ago. But Baden-Baden has really only come into its own during the last couple of centuries.

It lies in the valley of the Oos, a little river which winds through gardens and by the streets, sparkling in tiny cascades over a pebbly bed. Above the valley that holds the town, tower the protective hills that keep harsh winds at bay.

THE CLIMATE

One of the special appeals of Baden-Baden lies in a climate, the mildness of which ensures a perennial season. Winter may rule over the surrounding forest but its sojourn in the valley of the Oos is the briefest; rough winds are barred and banned for all times by hills thousands of feet in height. In summer the heat is agreeably tempered by the shade of the woods, by the wind and air currents carried from the hill tops through the town, by the river, and the evening breezes that arrive infallibly when the sun sets. These hills at Baden-Baden are covered with tropical gardens, wonderful forests and giant trees, a delight to the eye at all times.

THE SPRINGS

The waters of Baden Baden have a long and remarkable record and have been the source of healing for upwards of two thousand years. About twenty springs have their source on the slopes of the Schlossberg. They are mostly alkaline, radioactive, saline, thermal springs.

The great Friedrichs Spring pours out one million quarts every twenty-four hours, and the water is said to come from a depth of six thousand feet. The temperature is very high, 154° F. and the water is rich in lithium and arsenic. The Buttensource is one of the strongest radium springs in Germany. The most interesting aspect of the Friedrichspring is that it provides a novelty in the way of baths that can be had nowhere else. This is known as the *Wildbad*. Given in a shallow marble basin on a sandy bed, which retains the heat, it is very effective in the treatment of both gout and rheumatism and finds a continuous stream of patrons throughout the year.

There are the usual baths to be had; Turkish baths on the most elaborate scale; Fango baths, with volcanic earth from the Eiffel mountains (near the Belgian border); and carbonic acid baths, made by the addition of carbonic acid to the mineral spring water.

Another specialty of Baden is the Zander treatment, the famous system of exercises invented by Dr. Zander, of Sweden. These treatments are given in several of the Baden bath establishments and the largest of them has as many as seventy-four different machines for the exercise of certain muscles indicated and prescribed by the physicians.

THE CURES

Baden-Baden offers exceptional facilities for cures in surroundings that cannot be surpassed. The treatments given are for gout and rheumatism, especially inflammatory, catarrhs of the respiratory organs, and for certain troubles of the heart and nerves.

Aside from the regular bath establishments, a number of hotels provide medical bathing facilities in their own establishments, either in separate baths or private bathrooms, directly connected with the rooms of the guests.

ACCOMMODATIONS

On one side of the Oos is a long range of stately hotels, and, surrounded by lovely private gardens, inns, villas, boarding and lodging houses to suit all purses and all demands are ready to accommodate the traveler with the best they have to offer, and proffer an unfailing welcome that constitutes one of the principal charms of Baden-Baden.

AMUSEMENTS

The town affords the visitor the most generous variety of amusements. One of its great traditions is in offering the best in music that may be provided. A large municipal orchestra is on duty for eleven months of the year. Many of the most famous musicians of the past have played and sung here and the artists of today deem it an honor to be called to perform at Baden-Baden. There are first class plays, operatic performances, light and serious lectures, dances and other entertainments. The Kurhaus boasts of several magnificent ballrooms and the demand for dances is met here and at all the hotels.

Only a small percentage of those who visit Baden-Baden come for the sake of the cure alone. The social life is ever in the ascendant. All classes merge in the pursuit of a holiday and indeed Baden-Baden offers opportunities that will compare with those of any other inland holiday resort.

SPORTS

Nine hard tennis courts, a clubhouse and an instructor are provided for the tennis devotees in the valley of the Oos.

The situation of the golf links is admirable; there is a clubhouse and an instructor, annual tournaments with valuable prizes, and the social life of the links and the country-club. A short distance from the town, towards Lichtenthal, are excellent riding grounds for early morning canters.

First class whips, on old time coaches, may be seen any day on the roads and drives, and the race course at Iffezheim is world famous. For more than seventy years the "sport of kings" has annually attracted the multitude of the cosmopolitan sporting world.

Baden and its surroundings are a paradise for the motorist. Well made roads in all directions lead to places of attraction.

To the north and the south the wide fastnesses

Fig. 2.—Portion of old castle

of the Black Forest lure the motorist to excursions, to Freiburg, the Titise St. Blasien; Restatt, Pforzheim and Karlsruhe. Rivers and lakes, waterfalls on steep mountainsides, afford kaleidoscopic views of beauty to the motoring traveler.

Every year there is an automobile tournament in

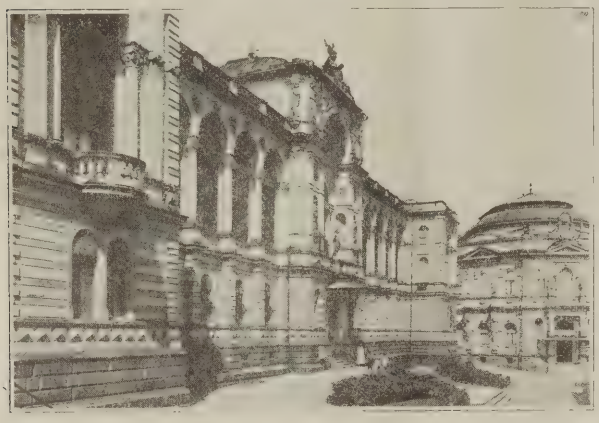


Fig. 3.—Friedrichsbad, with Augustabad in the background.

Baden-Baden and it has now become one of the most popular events of the season.

And last, but not least, there are the winter sports. The hills and the rivers, the lakes and the roads offer a variety of exhilarating exercise. From all parts of Europe and further, the lovers of winter sports assemble at Baden-Baden.

Thus, by its innumerable attractions, aside from its function as a health resort, Baden-Baden retains a firm hold upon a cosmopolitan gathering and maintains a reputation for social life that was established in the days of our great grandfathers and which will continue to grow from generation to generation.

News Items.

Shapleigh Memorial.—The St. Louis Medical Society has received from the family of the late Dr. John Blaisdel Shapleigh, the sum of $45,000 for a new auditorium, to be built as a memorial.

Research Endowment.—The National Academy of Sciences is raising an endowment fund of two million dollars to relieve scientists from teaching and permit them to devote their time to research in pure science. Dr. William H. Welch, of Johns Hopkins, is a member of the board of trustees.

Pneumonia Research.—Dr. William H. Park, of New York University, will direct a research endowed by ex-congressman Littauer, to be known as the Lucius N. Littauer Fund for Studies in the Prevention and Cure of Pneumonia. The endowment provides ten thousand dollars a year, and was presented through Dr. Jesse Bullowa.

Directory of Convalescent Homes.—A directory giving complete detailed information about convalescent homes serving New York City, has been prepared by the Hospital Information Bureau of the New York Academy of Medicine; a charge of twenty-five cents is made to private individuals for the directory.

Child Hygiene Exhibit.—An exhibition of modern hygiene and prophylaxis and the latest methods of applying gymnastics and developmental exercises for infancy and childhood, will open May 8th, at Dusseldorf, Germany, under direct supervision of Professor Dr. Schlossmann, of the University of Dusseldorf.

Hospital News.—The Passavant Hospital has been granted a ninety-nine year lease of space on the campus of Northwestern University, Chicago, on which it is to erect a new building, at a cost of one and a half million dollars. One third of the beds will be used for clinical instruction at the University.

The St. Luke's Hospital and the Children's Homeopathic are to merge. New Buildings with a capacity of three hundred and fifty beds will be erected at the present site of the Children's Hospital.

Gifts and Bequests.—The will of the late Gustav Ulbright provides $838,000 for the Lenox Hill Hospital, New York.

The will of the late Dr. Norman Bridge, of Chicago, divides his estate among the medical departments of the University of Chicago and the University of Southern California, the Barlow Sanatorium Association of Los Angeles, and two non-medical associations, each to receive about $1,200,000.

A gift of $250,000 has been received by the University of Pennsylvania from Mr. Martin Maloney of Philadelphia, as part of a fund to be raised for a new building for the University Hospital.

A gift of one hundred thousand dollars has been received by the Niles Hospital Association, Niles, Michigan, from Mr. and Mrs. F. J. Plym, for the purpose of buying and remodeling a building in the city for hospital use.

The University of Chicago has received a bequest of $600,000 from the estate of Miss Helen Culver, for the further development of biological science.

Personal.—Dr. Mark L. Fleming has been appointed general medical superintendent of Bellevue Hospital. Dr. Fleming has been connected with the hospital for twenty years.

Dr. Henry P. Carr, of the International Health Board, New York, will assist the Illinois Department of Health in the study of malaria in the rural districts of the state.

Dr. Robert Abrahams has been reappointed manager of the Manhattan State Hospital, for a seven years' term of service.

Dr. William Darrach, dean of the College of Physicians and Surgeons, has returned from a visit to the Columbia University School of Tropical Medicine in Porto Rico.

Dr. Herman G. Weiskotten has been appointed commissioner of health of Syracuse, New York, succeeding Dr. Thomas P. Farmer, who has resigned to enter private practice. Dr. Weiskotten is acting dean and professor of pathology of the Syracuse University College of Medicine.

Dr. William W. Keen, of Jefferson Medical College, Philadelphia, recently celebrated his eighty-ninth birthday.

Dr. Raymond P. Sullivan, of New York, has been honored by the insignia of a Chevalier of the Royal Crown of Italy, for his services to that country during the war.

Society News and Notes.

Among February meetings at the American Museum of Natural History will be those of the New York Microscopical Society on the 19th, the Section of Anthropology and Psychology of the New York Academy of Sciences on the 22d, and the American Ethnological Society on the same date.

* * *

On the evening of January 28th at the home of Dr. Jacques Maliniak, 258 Riverside Drive, several well known physicians of foreign birth met to discuss plans for forming an International Medical Association. Letters from physicians in or near New York who are interested in such an association will be gladly received.

* * *

The United States Veterans' Bureau Medical Officers' Society has elected the following officials to serve during 1926 in the New York City headquarters: Dr. F. M. Shockley, president; T. J. Ryan, vice-president; Dr. C. R. Brooke, secretary-treasurer.

* * *

The West Side Clinical Society of New York has elected the following officers for 1926: Dr. Jerome Kingsbury, president; Dr. George A. Schnepel, vice-president; Dr. George Stevenson, treasurer; Dr. William B. Giles, secretary.

* * *

The fifth lecture in the Harvey Society series was given on February 6th at the New York Academy of Medicine by Dr. Edwin Bidwell Wilson, professor of vital statistics at the Harvard School of Public Health. His subject was Empiricism and Rationalism.

* * *

The New York Röntgen Society met on February 8th at the New York Academy of Medicine. The speaker of the evening was Dr. Jacques Forestier, whose address was on the subject of Radiological Exploration with Iodized Oil.

* * *

In April, 1926, will be held a joint meeting of the American Statistical Association and the Vital Statistics Section of the American Public Health Association. The twentieth anniversary of the death of William Alexander King, first chief statistician of the vital statistics section of the Census Bureau, will be commemorated. Professor Willcox will address the meeting on the work of Dr. John Shaw Billings, which was closely related to that of Mr. King, and Mr. Van Buren, of the Metropolitan Life Insurance Company, will give personal reminiscences of the work of Mr. King in establishing the Registration Area and in planning for the adoption of the standard certificate of death in the several areas.

* * *

Dr. Foster Kennedy, attending physician of the Neurological Institute, New York, will lecture at the Academy of Medicine on the afternoon of Tuesday, February 23d, at four o'clock, on the Relation of Nervous Disorders to Functional Disease; on March 2d at the same place and at the same time, Dr. William A. White, of Washington, D. C., will speak on Psychological Methods of Cure.

The Malaria Commission of the League of Nations has recently issued its report covering observations and studies made during a tour in 1924 of many countries of Europe. In scope the report includes epidemiology, organization of antimalaria campaigns, measures adopted concerning man and those against the mosquito, the protection of houses, and the influence of animals, of improvements for the soil, and of population. The chief work of the commission was done in Italy and Southeastern Europe.

* * *

February meetings of interest are those of the Council on Medical Education and Hospitals of the American Medical Association in Chicago on the 15th to 17th; and the National Vocational Guidance Association in Washington, D. C., February 18th to 20th. On March 15th the Wyoming Public Health Association will meet in Cheyenne; the American Association of Pathologists and Bacteriologists will meet in Albany, April 2d and 3d; and the Western Physiotherapy Association in Kansas City, Mo., April 15th and 16th.

* * *

A members' meeting of the New York Microscopical Society at which various topics of interest were discussed was held at the American Museum of Natural History on February 8th.

* * *

An open meeting of the North Atlantic District of the American Association of Hospital Social Workers was held at the New York Academy of Medicine on February 3d. Hon. Louis I. Harris, Commissioner of Health of New York City, made the address of the evening.

* * *

The annual meeting of the American Social Hygiene Association was held on January 16th at the Hotel Pennsylvania, New York. More than two hundred members and delegates were present. Among the speakers were Dr. Louis I. Harris, Dr. Edward L. Keyes, professor of urology at the Carnell Medical School, and Dr. A. H. Desloges, general medical director for hospitals and other institutions of the Province of Quebec.

* * *

On February 3d H. Clyde Snook addressed the members of the New York Electrical Society on the subject of the stethoscope and other electrical devices developed by the Bell Telephone Laboratories for the aid of the medical profession.

* * *

The Community Health Council of the Bellevue-Yorkville Health Demonstration elected Dr. Louis I. Harris chairman at their meeting on January 14th. Other newly elected officers are Dr. John J. McGrath, first vice-chairman; Miss Lillian D. Wald, second vice-chairman; Miss Alta E. Dines, secretary; Dr. James Alexander Miller, chairman of the executive committee.

* * *

Prof. Henry Fairfield Osborn addressed the Section of Biology of the American Museum of Natural History on February 8th on the Problem of the Origin of Species as it was in 1859 compared with what it is in 1926. The lecture was illustrated with slides.

Book Reviews

THE HEART BEAT

The Mechanism and Graphic Registration of the Heart Beat. By Sir Thomas Lewis, M.D., F.R.S., F.R.C.P. Third Edition. London: Shaw & Sons, Ltd., 1925. Pp. 529.

This well known book, which needs no introduction to the discriminating student of medicine, is a monument to the life work of its author. First published fourteen years ago, it now appears in its third edition. The preface presents in masterful fashion the point of view which has underlain the scientific activities of Sir Thomas Lewis, and which has given him his high rank in medical science. A few quotations will reveal the character of the man and his work.

"The book was written originally in the hope that it might stimulate the study of heart affections by precise methods. Inexact method of observing, as I believe, is one flaw in clinical pathology today. Prematurity of conclusion is another and follows in part from the first, though in chief part an unusual craving and veneration for hypothesis, which besets the minds of most medical men is responsible. Hypothesis has its right place, it forms a working basis; but it is an acknowledged makeshift, and, as a final expression of opinion, it is an open confession either of failure or at the best of purpose unaccomplished. Hypothesis is the heart which no man with right purpose wears willingly upon his sleeve. I have been particular to set forth evidence upon evidence for a given conclusion in the book, feeling that no doctrine is sufficiently supported if yet another serious argument may be urged in its favor."

The book has been considerably rewritten and a number of new chapters have been added. Some of these are on the circulus movement in the genesis of auricular fibrillation and flutter, as well as of extrasystoles and paroxysmal tachycardia, on the membrane theory of electrical phenomena, and on the nature of heart block. There is no other book that presents in such lucid and complete form our present knowledge of the mechanism of the normal and abnormal heart beat, and in which the author's conclusions are so carefully supported by observation and experiment. Yet it is not only informative, but through emphasis on the limitations of our knowledge it is highly stimulating to the thoughtful reader. A bibliography of 1,003 references concludes the monograph. The volume is indispensable to every cardiologist and of the greatest interest to every practitioner of internal medicine.

REJUVENATION

Etude sur la Vieillesse et le Rajeunissement par la Greffe. Par Serge Voronoff. Paris: Gaston Doin, 1926.

The author, a well known pioneer in this new field of medicine, gives in the present small volume a summary of his work of the last years.

The introductory remarks are of general biological character and they show the author's earnest belief in the possibility of rejuvenation through transplantation. The main part of the treatise is taken up with the description of the various operations, their preliminaries, technic, immediate results and final clinical effects discovered after prolonged observations. The operations consisted chiefly of transplantations of ape testicles into men. He also has used sex glands of young animals for transplantation into old ones.

A short chapter is devoted to the prospects of rejuvenation of females by way of ovarian transplantation.

Voronoff's work as described in this volume compels us to respect the devotion and sincerity of the author. Although many of the theses and ideas set forth by him are in some ways still hypothetical and disputed, his efforts have doubtlessly done much toward overcoming prejudices against endocrinology in general and rejuvenation in particular and have helped to open and clear the road to further research.

A large number of excellent photographs, showing the various stages of the operations, as well as patients before and after the treatment, add much to the value of the book.

EARLY DIAGNOSIS OF TUBERCULOSIS

Frühdiagnose der Lungentuberkulose unter gleichzeitiger Berücksichtigung der Drüsen—und Lungensymptome. By Dr. Hans Alexander, Leitender Arzt des Sanatoriums Agra; 3rd Edition. Leipzig: Curt Kabitsch, 1925.

This is the third edition of Alexander's essay on the early diagnosis of tuberculosis. Prior to discussing the physical methods to determine the presence of tuberculosis in the lung, he emphasizes the fact that in taking the history, a primary infection and the whole physique of the patient with other intercurrent diseases, and his mode of life, must all be taken into consideration. Tachycardia, pain in the gastric region, anorexia, hyperhydrosis, loss of voice, easy tiring and anemia, besides cough and chest pains, he considers important symptoms in the diagnosis. He insists that the inspection of the chest should be made in good light and attention should be paid to the formation of the thorax, the presence of enlarged glands, etc. Measuring the chest circumference he considers of no value, nor does he believe the special palpation of the bronchial glands of particular importance. He elucidates the voice fremitus by the well known method of having the patient repeat in a deep voice the words *neun und neunzig* or *drei und dreizig.* The latter would hardly do of course if translated into English.

Pottenger's method of palpating for hypertonicity of the chest muscles, which the author calls "touch palpation," Alexander thinks does not differ from Epstein's *Tast Perkussion,* which had already been employed by Turban in lung percussion. He believes that this hypertonicity may be due to other causes besides being found over tuberculous lesions. Concerning percussion, nothing that is not already widely known is mentioned, but it is interestingly described. The author very wisely says that neither percussion nor auscultation can be learned from books and complicated instruments, such as phonendoscopes, etc., are not necessary for the normal ear. He insists that the best method of detecting auscultatory changes in the lung is the use of the monaural wooden stethoscope. He warns against

adventitious sounds produced by movements of the muscles, by pleuritic frictions, or by hair under the stethoscope. The importance of having the patient cough during examination he emphasizes by saying, "He who examines without having the patient cough commits an error in his art." He gives Turban's classification of the findings which may be obtained by auscultation. Like all careful diagnosticians, this author attaches the greatest importance to the temperature curve of the patient. He gives a short description of the quickest method of finding tubercle bacilli and enumerates the various tuberculin reactions without offering anything new. Concerning Wright's opsonic index method, he says that he believes it of value, but because of the difficult technic, it is impractical for the average physician. Concerning röntgen diagnosis he believes that while fluoroscopic examination may be helpful, only the actual photograph is of real value. He gives six interesting illustrations of various stages of pulmonary tuberculosis which will be of aid in the careful study of the interpretation of shadows produced by tuberculous invasion.

In spite of the whole work being comprised of only thirty-nine pages, of which four are devoted to the bibliography, this little booklet gives a good idea of what we ought to know about the early diagnosis of tuberculosis, and if the author would have devoted a little more space to the subject of differential diagnosis, the value of this contribution would have been greatly enhanced.

THE WRITING OF PRESCRIPTIONS

Prescription Notes. By Arthur L. Tatum, Ph.D., M.D. Chicago: The University of Chicago Press, 1925.

The author of this little booklet aims to teach correct Latin for prescription writing. I am afraid he will not succeed with those medical students who have not studied Latin, and unfortunately Latin is not now required as an entrance requisite by many medical schools.

The Latin suggested for prescriptions should be of the simplest. It would seem hardly worth while to change from the imperatives of *recipe, fac, signa,* and *pone* to the subjunctive *fiant,* which immediately confuses the grammatical construction. His criticism of *fac capsules* that the druggist does not make a capsule is perfectly true; but to be hypercritical we should not say under *signa,* "take one teaspoonful three times a day." It is more correctly stated, "take a teaspoonful three times a day."

Illustrative prescriptions should be distinctly useful, and it would seem very unusual to order "belladonna leaves"; a very rare use of belladonna. Also, when a soluble strychnine tablet can be ordered, the intensely bitter solution of strychnine sulphate in peppermint water would hardly seem satisfactory to the patient.

In the four rules for the computation of doses for children which are listed, the author apparently has not seen the simple rule offered in Osborne's *Principles of Therapeutics.*

The author's list of valuable preparations of the United States Pharmacopœia is excellent.

More than half the book consists of blank pages for the preservation of "selected prescriptions."

BIRTH CONTROL

The Morality of Birth Control. By Ettie A. Rout. London: John Lane, The Bodley Head, Limited. Pp. 224.

The Morality of Birth Control is not only a statement of the author's own feelings and opinions on the subject, but, and perhaps chiefly, a culling and weighing of the opinions of others who have written on the subject, and a statement of the facts as to the social influence and hygienic effects of the exercise of birth control and of its suppression.

"There is no period in human history," writes the author in her foreword, "when birth control measures have not been widely exercised, and there is abundant indication that prehistoric men and women habitually employed checks of various kinds. Only the uninformed will accept the claims of modern birthcontrollers to have 'discovered' something humanity was well aware of thousands and thousands of years ago; only the fraudulent will pretend that a practice which has survived so long is useless and dangerous; only the unintelligent will suppose that the knowledge of birth control now in the world can be taken out." This quotation summarizes the author's viewpoint in writing such a book and the chapters into which her discussion of the subject is divided ably support it. These chapters are entitled Reproduction, Race Improvement, Total Abstinance, Abortion, Unchastity, War, Ancient and Modern Birth Controls, Life Control, Death Control, Marriage, the Spread of Knowledge, Debate on Birth Control, and Conclusions. Appendices give French population statistics, quotations from an article on the Church and Married Love, by Lord Dawson of Penn, Birth Control Libel Action, and Emigration as an Alternative to Birth Control.

The nucleus of the author's whole argument is that race improvement is positive, not negative; that prevention of the birth of the unfit does not *improve* the race; it merely prevents deteriorating. "There is only one way in which the race can be improved, namely, by *constructive chastity.* Woman has innately the wisdom and power to select her proper mate; Man has the wisdom and power to reciprocate when he is chosen."

CHEMICAL PATHOLOGY

Chemical Pathology. By H. Gideon Wells, Ph.D., M.D., Professor of Pathology in the University of Chicago and in Rush Medical College. Fifth Edition, Revised and Reset. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 790.

In the five years that have elapsed since the publication of the fourth edition of Wells's excellent *Chemical Pathology,* the subject of biological chemistry has broadened its horizon to a considerable extent. This has necessitated the rewriting of much of the former edition, with the inclusion of two new chapters, but the present edition still shows the admirable selection and condensation that has always characterized it. Evidences as to the activity of laboratory research are abundant in this volume, for example, in discussing flocculation reactions in syphilis, one finds that since the 1920 edition five additional procedures for the detection of this disease have been included: the Meinecke reactions; Bruck's nitric acid reaction; the formol reaction; the Sachs-Georgi reaction, and the Vernes reaction. The enor-

mous amount of investigation which has been carried forward in the study of the deficiency diseases has made necessary a rewriting of much of this section of the book, and in this edition, due to the additional information obtained during the past five years, scurvy and rickets are now fully established as deficiency diseases. These illustrations cite but a few of the important changes in the text, so that to those who are familiar with the former editions of this work, this careful revision will be very welcome. It offers to pathologists, clinicians, chemists and medical students a most readable presentation of the subject of chemical pathology.

PROPRIETARY MEDICINES

Guide-Formulaire des Spécialties Pharmaceutiques. Par Dr. H. Legrand d'Amiens. Paris: J. B. Baillière et Fils, 1925.

This compact but rather extensive volume of upwards of eight hundred pages deals exclusively with what we would call proprietary medicines, their composition, indications, and doses. Our French colleagues seem increasingly devoted to the prescription of these therapeutic specialties in preference to the ordination of officinal preparations as specified and ordained in the respective formularies and pharmacopœias. As the specialties enumerated are all French, we are a bit at sea in looking them over, and are reminded of the American abroad, with a most inadequate linguistic preparation, who at a Paris restaurant picked out haphazard a number of apparently interesting culinary items, such as pot-au-feu, petite marmite, bouillon d'Alambert, bisque de tomates Maintenon, only to find himself surrounded by seven variations on a single theme—namely, soup! And so, one fears, it might be with *afatyl carrion, agar gigon, emplâtres vigier, ovo-lécithine billon,* or even *sparadraps beslier* and *soufre collobiasique dausse.*

CARBON MONOXIDE POISONING

L'Oxyde de Carbone et L'Intoxication Oxycarbonique: Etude Chimico-Biologique. Par Dr. Maurice Nicloux. Paris: Masson et Cie. Editeurs, 1925.

The frequency of poisoning at present from automobile exhaust has made the question of carbon monoxide a rather vital one. This volume contains a general survey of the sources of the gas, the symptoms of poisoning, its treatment, and the ordinary analytical methods used for the determination of its presence in air and in the blood. The bibliography is largely from French sources, and is fairly complete.

JESUIT MARTYRS

The Jesuit Martyrs of North America. Isaac Jogues, John De Brébeuf, Gabriel Lalement, Anthony Daniel, Charles Garnier, René Goupil, John Lanande. Illustrated. By John J. Wynne, S. J. N. Y. Universal Knowledge Foundation. Pp. 246.

This is the first complete and connected account of those men of the seventeenth century whose object in coming to this country and Canada was the conversion of the Indians to the Catholic faith. Their individual stories have been often told by word of mouth, or included as chapters in historical or religious works, but it has remained for this author to connect them as a whole in the historical backgrounds to which they belong.

The book shows an indefatigable zeal on the part of the writer to sift all authentic sources, historical documents and maps for proper material for making his history accurate and inclusive. The treatment is purely historical with a "religious" coloring. The portraits, other illustrations, and maps are good, and at the end is a long list of references and a bibliography of material on the subject.

The whole attitude of the author is, of course, that of the missionary, and his sympathy with the "savages" is that of uplifting them from their heathen state, with a total lack of understanding of their own manners and customs, and that they might have lives of their own, which they wished to lead. But the early Fathers of whom he tells us must have been men of unusual sympathy considering the times in which they lived, and their martyrdom was surely won through all the tortures of fire and the sword.

One of the chief interests of the book lies in the descriptions of this country at that time—the seventeenth century—and of the manners and customs of the various tribes of Indians that were undergoing conversion attended with so much agony to all concerned.

Medicoliterary Notes.

Peter the Czar, by Klabund, which has proved to be one of the most interesting of recent foreign novels, was written, according to press reports, by a man whose real name is Hensche. He is a small, delicate person with a lung complaint which makes it necessary for him to frequent Swiss health resorts. He is considered something of a mystery by his fellow countrymen, although he is well known in bohemian and dramatic circles. His play *Kreiderkreis* recently produced in Berlin, has proved a great success. It has a Chinese setting. His marriage was announced a few months ago to the leading woman of the Braslau Stadt Theatre.

* * *

The American Museum of Natural History had on exhibition during January an interesting collection of photographs of men and women of science. It is the property of Mr. Julian P. Scott.

* * *

That bees dance the Charleston, waltz, shimmy, tango and many dances with which human beings are unfamiliar, is the declaration Dr. von Frisch of the Munich Zoological Gardens, who maintains that bees do not dance as a means of amusement, but in order to tell their mates the location of newly discovered honey domains. By their gyrations, free and easy as classic Greek dances, they not only tell the direction of the new pasture, but also the distance and the kind of flowers, adds Dr. von Frisch, whose investigations have also proved that bees are practically colorblind, being able to distinguish gray, but unable to differentiate between other colors.—*N. Y. Times.*

* * *

Among interesting articles in the issue for January of the *American Journal of Public Health* are: The Engineering Aspects of Oyster Pollution, by R. E. Tarbett, sanitary engineer of the U. S. Public Health Service; Necessity for Changes in the Ventilation Laws of the United States, by Leonard Greenburg, Ph.D., associate sanitary engineer of the U. S. Public Health Service; and Qualifications for Public Health Nursing, the report of the Committee on Qualifications for Public Health Nursing Positions, presented at the annual meeting last October of the American Health Association.

* * *

Mental and physical disorders caused by vodka have become so prevalent in Russia since the introduction of a new forty per cent. variety, that the Soviet government has appointed a special commission to draft measures for dealing with intoxication. The number of stores selling liquor has

been limited to the neighborhood of factories, and the sale of vodka is restricted on Sundays and holidays. A heavy fine for drunkenness has been decreed. Many deaths have been caused by the new vodka and delirium tremens, hitherto practically unknown in Russia, is now prevalent.

* * *

New York is the first state to summon a safety congress. This will be held in Albany, March 11th-13th. Governor Smith will be honorary president. Commissioners of motor vehicles of seven states, officials of 110 cities, and representatives of the Federal and Dominion governments will participate in the congress, in addition to the leading safety experts of the country. Several large and very full exhibits of safety devices, traffic schemes, automobile devices, and many other kinds of equipment are being planned.

* * *

The *American Journal of Public Health* for January has for a supplementary section the report of the Committee on Municipal Health Department Practice, including a revised appraisal form for city health work.

* * *

The Mayor and Deputy Mayor of Stoke-upon-Trent, one of the "Five Towns" of Arnold Bennett's series of novels on that subject, are up in arms against the novels as untrue criticisms of the district. They accuse Bennett of exaggeration and distortion and say that the novels will damage the prestige of the Five Towns, and that they are libels of both the people and the localities. Other municipal officers of the district, however, scout these claims and call the novels true pictures of the places and their inhabitants. This contest is of especial interest now that a complete edition of all the "Five Towns" novels, similar to that of Galsworthy's *Forsyte Saga,* has been announced by the publishers.

* * *

A woman aged 146 years, with her son of 117 years, have been found living in the mountains of Persia, according to the London *Daily Express.* The discovery was made during the taking of Persia's first census. These two are close seconds to the oldest man in the world, a Turk who is registered as being 150 years of age, and who was last married at the age of 142.

* * *

The Biology of Population Growth, by Raymond Pearl, is one of Alfred A. Knopf's recent publications.

* * *

The Joint Committee on Methods of Preventing Delinquency is distributing copies of *The Relation of Social Work to Psychiatry,* by Dr. Ralph P. Truitt, director of the Division on Prevention of Delinquency of the National Committee for Mental Hygiene. These may be obtained without charge from the Joint Committee, 50 East Forty-second Street, New York City.

* * *

The discovery of serums preventing blood poisoning, erysipelas, puerperal fever and other disorders has been announced by the University of Leningrad. The discoverer is the professor of bacteriology at that institution, Dr. Sergius Zabolodny. In preparing the serums use is made of what are called "aromatic bacteria," which are said to possess the property of dissolving albuminous substances in the body.

* * *

Vanity Fair for February contributes several articles of interest to the medical profession. The first of these is entitled A Few Well Chosen Words, by Aldous Huxley, who contends that "words are dangerous as well as useful. They have made it possible for us to organize our thought; but they have made it impossible for us to think except in terms of language." With this as a text, Mr. Huxley proves his case with illustrations of what he terms "dangerously moving words," as, for instance, the word sex, which in many countries arouses a very definite reaction. However, in India the word beef arouses much stronger emotional reactions than sex with us, on account of the many local food taboos. The article is a valuable contribution to word psychology. Other articles of interest are The Psychology of Acting, by A. B. Walkley; Art and Morality, by D. H. Lawrence; and The Dance Mania, by Dr. Joseph Collins.

Because so many of its employees have lost their lives from the inhalation of poisonous gases in the Montier Grandval tunnel in Switzerland, the Federal Railway Company has provided gas masks like those used during the war for engine drivers and guards on freight trains which pass through the tunnel. It is stated that there is no danger on the passenger trains as these have a much greater speed. The Swiss press, however, is demanding immediate electrification of the line, which is the highway to the winter sports region.

Two interesting sociological and ethnological studies have recently been issued by the Association for the Study of Negro Life and History, Incorporated, with headquarters in Washington, D. C. These are entitled, respectively, Free Negro Heads of Families in the United States in 1830, and Free Negro Owners of Slaves in the United States, Together with Absolute Ownership of Slaves in the United States in 1930. Carter Godwin Woodson, editor of the *Journal of Negro History,* is the author of both studies.

* * *

The British Museum has recently put on exhibition a statuette of Socrates, made of Parian marble which is said to be the only sculptured full length figure of the great philosopher made within a reasonable time after his death. It was discovered at Alexandria and has been declared to have been made in the fourth century, B. C. He is shown with the characteristic very snub nose, but not completely bald as is the case with so many other representations of the great Athenian.

* * *

The many New Yorkers who enjoyed the productions of the Moscow Art Theater will be distressed to learn that its able director and its greatest actor, Constantin Stanislavsky, has been stricken blind.

* * *

Animal Heroes of the Great War, by Ernest Harold Baynes, is one of Macmillan's most interesting recent publications. To secure the material for his book, Mr. Baynes travelled for nine months in Europe, Egypt and Palestine. The stories deal with the great draught horses, the cavalry horses, the camels, mules, oxen, dogs and carrier pigeons. All lovers of anmals will find the book entrancing.

* * *

One of the books of the month is Ted Shawn's The *American Ballet,* with an introduction by Havelock Ellis, published by Henry Holt & Company. Another publication from the same firm is Milton Waldman's *Americana,* which has been described by a well known critic as "the first careful and adequate treatment of the *materials* of our history." Mr. Waldman, although editor of the *London Mercury,* is an American.

* * *

The Massachusetts Society for Mental Hygiene began in November the publication of a new bulletin called *The Human Factor,* devoted to every day problems of industrial relations as they relate to mental health. It is issued especially for busy executives, personnel workers, educators in stores or factories, physicians, and all other persons who are in any way concerned with the human factor in industry. The articles are non-technical and popularly written, and the material presented is sound and authoritative.

* * *

The European press reports an epidemic of trachoma so prevalent in several sections of the Palatinate that schools have been closed to prevent the spread of the disease. One of the explanation advanced for the epidemic is that the disease was introduced by the Moroccan troops of the occupation forces.

The city of Vienna, justly famous for its beauty, its art, and its music, has recently been the centre of attraction for all interested in the questions of health. The Health Exhibition was opened there on the 28th of April last by Dr. Hainisch, President of the Austrian Republic, and was housed in the vast buildings of the Messapalast, which at one time was used as the imperial stables. These buildings are situated in the very heart of the city and have been specially adapted for such occasions. Here the different aspects of public health were vividly presented in such a manner as to appeal not only to the technical mind but to the uninitiated as well. The loan by the Dresden Museum of Health of its interesting collection of material relating to human anatomy and physiology was much appreciated and contributed in no small measure to the success of the exhibition.—*World's Health.*

Abstracts from Current Literature

GYNECOLOGY AND OBSTETRICS

Influence of Pregnancy upon the Lipoids of the Blood. Margaret Tyler and Frank P. Underhill (*Journal of Biological Chemistry,* November, 1925) found that beginning as early as the third month in pregnancy the total ether extract of whole blood of pregnant women is higher than that of nonpregnant women, the increase being progressively augmented until term. Cholesterol, cholesterol esters, and lecithin increase gradually until term, when each is approximately one third higher than at the third month of pregnancy. During the period of pregnancy, the relation of cholesterol esters to the total cholesterol remains fairly constant, and the esters form a larger percentage of the total cholesterol than obtains in nonpregnant women. The relation of lecithin to cholesterol remains fairly constant during pregnancy, and is at all times within the normal limits for that value in nonpregnant women. During the first two weeks of the puerperium the values for the ether extract and for the individual lipoids of whole blood remain high.

Exclusive Röntgenotherapy of Carcinoma of the Cervix Uteri.—Friedrich Voltz (*Klinische Wochenschrift,* July 16, 1925) made a statistical study of 755 cases of carcinoma of the cervix uteri treated only with irradiation therapy and draws the following conclusions:

The results of exclusive irradiation therapy may well be favorably compared with those from surgical treatment. In a certain respect they may even exceed the results from surgery, because the former may still produce results when the latter is futile. The excuse for a return to surgery because we have no positive indications for a successful irradiation therapy is no longer tenable; where none are available they must be ascertained. The claim that irradiation therapy gives a greater number of recurrences than does operation is not true. The reproach that a case of carcinoma that has been cured by röntgenotherapy could have been cured just as well by operation is equally false. On the contrary, statistics show that every carcinoma of the cervix that can be cured surgically can be cured equally well by irradiation. In fact, irradiation therapy can even cure inoperable carcinomas, which surgery cannot do. While it is true that there is still much to be learned in regard to irradiation therapy, if only inoperable cases were subjected to irradiation therapy we would gain the wrong picture of its possibilities. In order to develop and improve our methods we must also use irradiation in operable cases. This procedure is justified by the statistics on the results already obtained.

Retention Catheter in Pyelitis of Pregnancy.—J. O. Rush (*Surgery, Gynecology and Obstetrics,* March, 1925) states that pyelitis and pyelonephritis are pus conditions, and will respond to drainage as do pus conditions in any other portion of the body, and (indwelling) retention ureteral catheter is the method of choice. In all cases of pyelitis and pyelonephritis, even in children, the retention ureteral catheter is preferable to other forms of treatment. Catheter drainage is preferable to lavage with drugs, since the strength of the drug used is insufficient to kill the organism producing the disease. It is my opinion that the passage of catheter by its dilatation of the ureter is what benefits the patient in lavage and not the drug used. I believe sterile water will produce as good results in lavage as nitrate of silver. No surgical procedure should ever be resorted to until catheter drainage has been given a most thorough trial. The finest quality imported x ray catheter should be selected for this work. Urinary deposits have never been found on this type of catheter, even after it has remained in the ureter twenty-six days.

A Study of the Gram Positive Cocci Present in the Vagina and Cervical Canal of the Uterus.—Lloyd Arnold, and Louis Brody (*Journal of Laboratory and Clinical Medicine,* April, 1925) isolated one hundred and seventy strains of gram positive cocci from the vaginal tract, forty-eight staphylococci, sixty-six enterococci, and fifty-six streptococci, two hundred and sixty-two strains were isolated from the cervical canal of the uterus, seventy staphylococci, ninety-six enterococci, and ninety-six streptococci. The vaginal bacterial flora resemble in many respects certain fecal types. The gram positive cocci of the cervical canal differ from those found in the vaginal tract by a gradual loss of the power to ferment mannite, so typical of strains of fecal origin, and they become more pathogenic for mice. The average limiting hydrogen ion concentration was 5.0, the variations being between 4.7 and 5.6, so they were all within the human or pathogenic range. This the authors believe to be a result of the contact of these strains with the exudation present in the cervix and vagina of the cases studied.

Advantages of the More Conservative Operation for Myoma of the Uterus Over Radical Operation and Röntgen Castration.—B. Aschner (*Wiener klinische Wochenschrift,* June 18, 1925) says that the destruction of the menstrual flow by extirpation of the uterus, especially the supravaginal amputation and röntgen castration (and also radium irradiation) leads by no means not only to the frequently indifferent and transient socalled premature climacterium, but often is followed by sereve and sometimes life endangering and life shortening general diseases, such as hypertonia, arteriosclerosis, gout, nervous diseases, psychoses, and apoplexy.

Atypical uterine hemorrhages, such as hemorrhagic metropathia, hemorrhages of puberty, climacteric hemorrhages, and the like, can be cured almost always by general treatment, such as regulation of the metabolism, the digestion and the circulation (bloodletting), in addition to rest in bed, styptics, and curettage.

Extirpation of the uterus, and especially, supravaginal amputation and röntgen irradiation are almost always dispensable in hemorrhagic metropathy and dangerous to the general condition whenever they can possibly be avoided.

In myoma, even with very large and very numerous tumors, the retention of a uterus fully capable of menstruation to the fullest extent up to the latest climacteric age should be the goal as regards the general condition and is almost always attainable. The radical methods of operation (supravaginal amputation and total extirpation) and the röntgen castration for myomas should be limited as much as possible because of their injurious effects on the general condition and replaced by the conservative myoma operations (enucleation, enucleation resection), as long as there exists a menstrual flow.

Infundibulin: Indications for Its Use in Surgical and Obstetrical Practice.—W. Blair Bell (*British Medical Journal,* June 6, 1925) advances certain general contraindications to the use of infundibulin. It should not be administered during an operation if there be respiratory failure, for the normal amplitude of respiratory movements is diminished by it. When there is myocardial or valvular disease of the heart without complete compensation infundibulin is absolutely contraindicated. A fatal issue may follow the exhibition of a small dose. Even in the presence of compensation it is a dangerous drug to employ. In renal disease associated with a high blood pressure the use of infundibulin is inadvisable.

In the prevention of shock much can be done by the use of infundibulin in debilitated patients with low blood pressure. The administration of this extract several times daily for several days before a serious operation, undertaken in septic or cachectic cases, often enables the patient to withstand the traumatic effects of operation and the toxemic effects of the anesthetic. In cases where the falling blood pressure during an operation denotes deterioration before any other evidence is available, infundibulin may save the situation. In cases associated with a certain amount of trauma from the separation of adhesions, the subsequent paralytic distention may be prevented by the intramuscular injection of 0.5 c. c. of infundibulin every few hours in the aftertreatment. In order to obtain a certain pressor effect on the intestinal muscle, 1.0 c. c. should be administered, followed by a turpentine enema. In acute dilatation of the stomach, this organ should be washed out ten minutes after infundibulin has been injected. Infundibulin is contraindicated in these complications if an operation involving repair or anastomosis of the stomach or intestines has been performed, and, of course, if unrelieved obstruction be present.

When there is atony of the musculature of the bladder with distention a pressor effect and evacuation may follow

an injection of infundibulin, but this result is somewhat uncertain. The inability to empty the bladder after gynecological operations and after parturition may generally be overcome by the judicious use of infundibulin (1.0 c. c.) and a catheter.

In the termination of pregnancy, the indications may be classified as follows: 1, for the expulsion of a dead child; 2, in order to obviate the possibility of disproportion between the maternal and fetal parts; 3, in the treatment of antepartum hemorrhage. In the first two groups, infundibulin administered every four hours for several days in doses of 0.5 c. c. occasionally precipitates labor; but such an event is comparatively rare unless the patient be at term or the child is dead. In cases of postmaturity it is very wise to give the extract as indicated. The first method of treatment in cases of accidental hemorrhage in which the bleeding is not entirely concealed, and in which there are indications for interference, consists of rupture of the membranes and an injection of infundibulin. In accidental hemorrhage which is entirely concealed, it should not be employed until the uterus has been emptied. In placenta previa, especially when the implantation is not central, infundibulin may form a valuable adjunct to other methods of treatment, such as rupture of the membranes. In ordinary cases of Cæsarean section 0.5 c. c. of the extract should be injected into the triceps of the patient after the uterine wound has been sutured, if retraction appears then to be incomplete. When Cæsarean section has been done for concealed accidental hemorrhage and the uterus has been preserved, a few cubic millimetres should be injected directly into that organ.

In primary uterine inertia of the physiological type, we should never administer infundibulin, for it is not required, and, unless the diagnosis be accurate, serious trouble may follow. In pathological primary uterine inertia (with low blood pressure) and a normal uterine musculature, 0.5 c. c. of the extract is administered intramuscularly two or three times daily. In secondary uterine inertia due to exhaustion of the uterine muscle, infundibulin is of considerable help.

The only scientific indication for infundibulin during labor is the evidence, readily obtainable, of insufficiency of this substance in the blood. This evidence consists of a history of protracted labor, with gradually diminishing force and frequency of the previously normal contractions and the state of the blood pressure. During labor an initial dose of more than 0.25 c. c. intramuscularly should never be given, and later doses should not exceed 0.5 c. c. The contraindications during labor include any disproportion between the fetal and maternal parts and the presence of efficient uterine contractions. The routine use of infundibulin as soon as the second stage of labor is over to hasten the third stage is neither scientific nor expedient. It may, however, be used advantageously after the expulsion of the placenta, when uterine inertia has permitted postpartum hemorrhage.

Puerperal subinvolution of the uterus may be effectually treated by the administration of infundibulin—the sooner the better.

Spontaneous and Artificial Changes in the Menstrual Rhythm.—R. Hofstätter (*Wiener klinische Wochenschrift,* June 6, 1925) states that the relationships between ovulation and menstruation are certainly less constant than has been believed heretofore. In addition to the spontaneous and probably very regular ovulation, there is also an induced ovulation in the human being. Spontaneous ovulation occurs probably only then when the maturing follicle has not been induced to expel its ovum before that by sufficiently powerful stimuli, usually of a sexual nature.

The not very infrequent change of a menstrual wave to another period might be explained in a way, that an induced ovulation leads to another uterine bleeding by some additional accidents that are not always recognized by us, or in this way, that a bleeding produced in a vasomotor fashion or possibly as a result of a curettage acts in a similar manner upon the whole organism to a normal menstruation. In this way such a bleeding can to a certain extent fulfill all the functions of a normal menstruation and bring the uterus to the zero point of its cyclic function, so that in accordance with its accustomed rapidity of regeneration of the mucosa it again takes four weeks until a pregravid change degenerates with the omission of the awaited nidation of the ovum. The corpus luteum produces neither the menstruation nor does it retard it. The fact that an impregnation may occur at any time in spite of a normal menstruation can hardly be explained in any other way than by the assumption of the possibility of an induced ovulation in addition to a spontaneous ovulation.

Relationship of Neonatal Morbidity and Mortality to the Toxemia of Pregnancy.—I. A. Abt (*Archives of Pediatrics,* July, 1925) investigated 210 mothers suffering from toxemia of pregnancy. Toxemia occurred more frequently in primiparous than in multiparous mothers. Thirty-nine infants were born dead; twenty-seven were stillborn; twelve were macerated. In this series of cases, eighty-two were born full term, one hundred and twenty-two were more or less premature; in twenty cases the information was not obtained. Infants who were born of eclamptic mothers showed diffuse hemorrhagic areas and also anemic and hemorrhagic necroses in the various organs, which are similar to the pathological changes found in eclamptic mothers. Blood and albumin have been found in the urine of these infants. Necrosis of the liver cells is sometimes observed. The neonatal mortality in this series was 24.77 per cent. The maternal eclampsia did not seem to effect a permanent injury in infants who have survived. Infantile convulsions occurred only five times, but it is to be remembered that many of the mothers who had convulsions gave birth to stillborn children shortly after the eclampsia. Congenital malformations occurred eight times. It is possible that maternal toxemia occurring early may favor fetal malformations.

Outlook for the Fetus with Pyelitis of the Mother.—H. Naujoks (*Zentralblatt für Gynäkologie,* May 23, 1925) recalls that the children of pregnant women suffering from pyelitis are threatened by serious danger and that many pregnancies do not reach their normal ending; it is only rarely that a plausible explanation for the intrauterine death of the fetus can be found, and especially in the investigation of the causes of repeated abortions we are forced to advance theoretical speculations, for which clinical or experimental proof has not as yet been advanced. A definite basis for an etiological therapeutic procedure is therefore not available. The only possible procedure in these cases is the earliest possible thorough treatment of the pyelitis of pregnancy along the lines of general dietetic and drug therapy. In the vast majority of cases the patients readily respond to this treatment and steadily improve. Only after the complete failure of conservative measures is active therapy, which is not very gentle and absolutely harmless, indicated. All local measures must be exhausted before interruption of pregnancy in the interest of the child is undertaken. The interruption of pregnancy should be the last resort and undertaken only after serious consideration pro and con. Opinions differ regarding the possibility and advisability of avoiding a nephrotomy by the induction of abortion. The operation on the kidney during pregnancy, which primarily takes into consideration only the fate of the child, often leads to a spontaneous interruption of the pregnancy later and may lead to serious danger during the puerperium as a result of the long continued suppuration. It deserves consideration at best only when artificial abortion is not available.

Shoulder Pain in Ruptured Ectopic Gestation.—A. E. Roche (*Clinical Journal,* June 3, 1925) emphasizes shoulder pain as of diagnostic interest.

The following points deserve notice: 1. In four out of five cases of ruptured ectopic gestation pain was felt in the region of the shoulder. 2. In all four cases the shoulder pain was preceded by abdominal pain. 3. In favor of this shoulder pain being caused by stimulation of the phrenic sensory fibres by blood which has travelled up to the diaphragm are the following facts: In the first patient there was no more pain in the right iliac fossa after the operation, but the pain in the shoulder continued for twenty-four hours, preventing sleep. In this case a little blood adhering to the diaphragm may well have sufficed to maintain the shoulder pain, especially as the procedure of swabbing the peritoneum free from blood, which was performed in its lower part, is impossible to carry out in its upper part. The fifth patient, with preoperative pain in the left shoulder region, complained, on the day after operation, of stabbing pains in the right side over the seventh and eighth ribs on breathing. There was no cough, nor any signs in the chest, and the pains had gone by the next day. These can be explained, pleurisy and pneumonia

being out of the question, by the displacement of blood by operative manipulation stimulating intercostal nerves. The sixth to twelfth dorsal nerves provide the sensory supply to the margin of the diaphragm. In the fourth patient sudden shoulder pain actually developed during abdominal palpation, this phenomenon being quite consistent with the upward manipulation of blood so as to impinge on the diaphragm. 4. In the first two patients with pain in the shoulder region the flanks were resonant, although the peritoneal cavity contained large quantities of blood. In patients, then, suspected of harboring ruptured tubal gestations, the presence of shoulder pain should be regarded as an extremely valuable sign of free peritoneal blood (in fact, of blood having hit the diaphragm), and as equal or superior to percussion of the flanks as a diagnostic aid, while less disturbing to the patient. 5. In one case the right shoulder was painful when the left tube was ruptured, in another the left shoulder was painful when the right tube was ruptured, the side on which the shoulder is painful thus not serving as a clue to the side of the ruptured tube. This, however, does not detract from the value of this symptom, as the important thing to diagnose is not the side, but the fact of the rupture.

Hyperemesis Gravidarum.—H. O. Howitt (*Canadian Journal of Medicine and Surgery,* January, 1925) reports a case of this nature in which the patient was apparently approaching death, a change for the better followed almost immediately the commencement of treatment, and her condition continued to improve rapidly to recovery. The treatment consisted of 1, rest in bed; no visitors; 2, the giving of intravenous saline; 3, sodium bromide drips per rectum every four hours added to or alternating with drips of sodium bicarbonate; 4, the use of insulin, five units three times a day.

Pneumoperitoneum in Diagnosis of Early Pregnancy.—L. E. Burch (*Surgery, Gynecology and Obstetrics,* May, 1925) presents his operative technic and concludes from his experience that for obscure pelvic lesions and early pregnancy determinations inflation of the peritoneum by either the abdominal or uterine route is perfectly safe in cases in which there are no contraindications. There is very little pain if the patient is kept in the kneechest or Trendelenburg posture during the inflation and for fifteen minutes after it. The method is of the greatest aid in obscure pelvic cases and will make an accurate diagnosis possible. It is possible to diagnose with certainty pregnancy in the early weeks, provided the pathognomonic sign mentioned in the paper is shown in the röntgenogram.

Sedimentation Test in Gynecology.—J. L. Baer and R. A. Reis (*Surgery, Gynecology and Obstetrics,* May, 1925) find that the sedimentation test is apparently of no value in the early diagnosis of pregnancy. 2. It is useful in determining the presence or absence of infection in the body. With pelvic pathology, a negative sedimentation test (a sedimentation time over two hours) conclusively rules out pelvic infection. 3. The rate of sedimentation is directly proportional to the virulence of the infection. 4. The test is a further aid in determining the safe time for operation. 5. The sedimentation test seems a more delicate prognostic index, good or bad, than either the leucocyte or temperature curve.

Degeneration of Fibromyomata of the Uterus.—L. Seed (*Surgery, Gynecology and Obstetrics,* September, 1925) finds that gross degeneration occurs in approximately thirteen per cent. of fibromyomata. Edematous, cystic, and myxomatous degeneration are a part of the same pathological process, probably due to a gradual diminution in the blood supply. There are no clinical symptoms peculiar to it.

Red degeneration is an aseptic necrobiosis characterized by fatty degeneration, thrombosis of the vessels, extravasation of red blood cells, and blood pigment. Pathologically it is a "red infarction," and can be explained by a sudden complete vascular obstruction affecting chiefly the venous system. The end result is a total fatty necrosis with transformation of the hemosiderin into hematoidin, and subsequent calcification. The occurrence of symptoms depends on the size of the tumor and the acuteness of the necrosis. There is local pain and tenderness, and a mild toxemia.

Infection following necrosis of a submucous fibromyoma is very distinctive and probably accounts in itself for all symptoms.

Calcification has little clinical significance.

Cæsarean Section in Obstetrics.—A. J. Rongy (*International Journal of Medicine and Surgery,* September, 1925) finds that Cæsarean section, as a method of delivery in cases of placenta previa, is not, as yet, accepted by the medical profession generally. It is surprising how such cases are still badly mismanaged. The majority of them reach the hospital in a badly exsanguinated state. However, he does not know of any method of treatment other than a rapid abdominal delivery that will control the bleeding in a patient who is suffering from a placenta previa before labor has actually set in. The uterine cavity is packed with iodoform gauze in order to prevent postpartum bleeding, and the uterine and abdominal wounds are closed in the usual manner. Blood transfusion may be given, if found necessary. It will certainly enhance the convalescence.

The author is strongly convinced of the necessity, in all bleeding cases, to have the patients, in the last two or three months of pregnancy, transferred to the hospital. It has been his experience that patients suffering from eclampsia, who are not in labor, who are steadily growing worse because of frequent convulsions, and in whom the condition of the soft parts renders the operation from below dangerous, are best treated when they are delivered by the abdominal route.

Women who suffer from heart disease can and should be delivered by Cæsarean section under local anesthesia in the thirty-seventh or thirty-eighth week of pregnancy, thus saving them the strain of labor and the tax that the last few weeks of pregnancy puts upon the heart; furthermore they can be sterilized if deemed necessary.

There is very little postoperative disturbance when the operation is done under local anesthesia. It must be done quickly and the uterus must not be lifted out of the abdominal cavity. Pulling and dragging of the uterus causes the patient a great deal of pain and discomfort. Assisted by an efficient staff, the time consumed in the performance of such an emergency operation should not last longer than ten to fifteen minutes.

The elderly primipara is becoming more and more of a problem to the obstetrician. In many of these patients the cervix is thick and hard. Dilatation, if it takes place at all, is very tedious and often complete inertia sets in before the dilation is complete. The problem then arises as to what method of delivery should be chosen. The author is fully convinced that the abdominal route of delivery will conserve the greatest number of mothers and children in this group of cases.

Treatment of Abortion.—H. K. Tuttle (*Surgery, Gynecology and Obstetrics,* January, 1925) concludes from a tabulated report of cases that:

1. Abortion of any type is a serious condition and operative treatment should never be considered lightly. Unless proper hospital facilities and operative technique are available the condition had better be treated expectantly.

2. Hemorrhage sufficiently severe to call for immediate active treatment is seen in approximately five per cent. of all cases. Attention is called to those cases with little or no external bleeding that pass large clots at intervals which, if passed unobserved, will soon bring the patient to a dangerous condition from hemorrhage or lowered resistance to infection.

3. The records of this hospital show that febrile abortion cases operated upon promptly have slightly higher average number of postoperative febrile days, a lower per cent. morbidity, and fewer average hospital days than those operated upon a number of days after the temperature has remained normal. The average febrile days, morbidity percentage, and average hospital days of operative cases are lower than in the nonoperative. We believe that in the ordinary incomplete abortion the sooner the uterus is emptied the shorter will be the convalescence. Many cases will be discharged from the hospital at the end of a five day period.

4. The treatment of septic abortion requires mature judgment. Those cases where infection has extended beyond the uterus, and without evidence of retained necrotic placenta or membranes should be treated expectantly. However, in our opinion when such tissue remains in the uterus it is just as essential to remove it as a sloughing appendix in the abdomen, provided the removal can be accomplished without spreading the infection. Both are sources of infection so long as they remain *in situ.*

5. Surgical treatment is difficult to standardize and no one method will apply equally to all cases.

PEDIATRICS

Skin Temperatures in Normal Children.—From a study made of five normal children, Fritz B. Talbot, with Alice Johnson Dalrymple and Mary F. Hendry (*American Journal of Diseases of Children,* October, 1925) found indications that the skin as an organ has some power to prevent loss of heat as well as to accelerate loss of heat by perspiration.

Skin Temperature and Basal Metabolism During Fasting.—In another paper based on an examination of four children suffering from idiopathic epilepsy who underwent fasts of seven to fourteen days duration, the same authors say that they observed that the rate of heat production diminished in proportion to the fall of skin temperature; and the longer the fast the greater the fall of temperature.

Importance of Considering the Body Mechanics of Children.—Lucy Porter Sutton (*American Journal of Diseases of Children,* October, 1925) urges that body mechanics be considered in the examination of every child. Correction of faulty posture in childhood gives the best results and frequently remedies conditions such as constipation, irritability and poor appetite.

Some Experiences in Mental Reconstruction.—Alice Hinckley (*Archives of Pediatrics,* September, 1925) in work undertaken primarily to discover causes of failure of children to complete the grammar grades gives five interesting instances of children, aged from three to eleven years at the time of their special tutoring under her direction started, and describes the positive improvements made. All the children began with some serious form of sensory motor interference which would ordinarily be looked upon as quite beyond expectation of change.

Effect of Heat on the Solubility of the Calcium and Phosphorus Compounds in Milk.—Raymond W. Bell (*Journal of Biological Chemistry,* June, 1925) used in all these experiments fresh, raw, skim milk, heated to various temperatures to study the effect of heat on the solubility of the calcium and phosphorus content. Pasteur-Chamberland filters and a high speed supercentrifuge were used. There was apparently a loss in the soluble calcium and phosphorus contents of the skim milk due to heat, the amount of the loss depending upon the temperature to which the milk has been heated. The results from the methods employed indicate that definitely measurable amounts of these substances are removed from solutions in milks heated to 170° F.

Comparative Nutritional Value of White and Whole Wheat Flour.—C. Ulysses Moore and Jessie L. Brodie, by an experiment on mice in the University of Oregon Medical School (*Archives of Pediatrics,* September, 1925) call attention to the superiority of whole wheat over white or patent flours, not only from the viewpoint of health and life but also of economy.

Gastric Digestion in Newborn Infants.—C. Griswold and A. T. Shohl (*American Journal of Diseases of Children,* October, 1925) in a study of twenty-five normal infants have observed a greater capacity for digestion in newborn infants than later in infancy. The gastric juice of unfed newborn infants contains free hydrochloric acid, the average ph being 2.6. The digestion of fifty c.c. of partly skimmed cow's milk was practically complete in one hour.

Microcephalus with Report of Case.—In a report (*Archives of Pediatrics,* September, 1925) Joseph H. Marcus describes a case of microcephalus in a nine months' old infant where convulsions were caused by gradual and constantly increasing intracranial pressure which led to death.

In a general discussion of the subject Dr. Marcus says that the life of a microcephalic may extend into adult or even advanced years as the physical health is usually not amiss. On the whole the mental prognosis is in proportion to the size of the head. With heads under eighteen inches in circumference, the manifestation of mental power is usually so small as to come under the category of idiocy; between eighteen and nineteen inches, the cases may be designated as imbecile; and from nineteen to twenty inches is not an uncommon measurement in cases of mere feeblemindedness. There is hope of improvement under training, especially for the higher grades of this type. The operation of craniectomy, recommended in 1890 in microcephalus cases, has been abandoned because of disappointing results and the knowledge that the small skull is simply moulded to the brain, the development of which has been arrested at the fifth month of intrauterine life.

Three Case Reports.—These case reports are given by D. Lesesne Smith (*Archives of Pediatrics,* September, 1925) to emphasize the importance of obtaining a thorough history as to the foods, as well as the drugs, that a nursing mother is taking when presenting her child for examination. An unexplained severe rash on an infant of four months was discovered to be due to Peacock's bromides which the mother had been taking during pregnancy and since the birth of the child. Another mother, interpreting some general advice as to diet, had been taking four raw eggs and three cooked ones every day. As soon as the eggs were discontinued the infant's rash cleared up. The third case was of a mother who had also been taking bromides in large quantities.

Amyotonia Congenita.—John Aikman presents two and probably three cases of amyotonia congenita to add to the literature, all females and in the same family (*Archives of Pediatrics,* October, 1925). The first girl died at five months, the second at nineteen months and the third at seven months. The first two had had very slight movements of hands and legs or none at all while the third appeared normal until the age of two months when she, too, stopped kicking and moving her arms and began the abdominal type of breathing.

Heat Exhaustion in Infancy and Childhood.—Adolph G. DeSanctis and Frank Shapiro (*Archives of Pediatrics,* September, 1925) find that heat exhaustion or thermic fever as a direct cause for morbidity and mortality in infancy and childhood has been greatly underestimated. In hot spells we hear in the papers of adults succumbing to the heat; according to the authors it is clear that children also die from the same cause in proof of which two instances are cited.

A Case of Meningitis Caused by the Meningococus and the Paratyphoid B. Bacillus.—A case of meningitis caused by two different organisms, the meningococus and the paratyphoid B. bacillus is recorded beacuse of its rarity by Emanuel Appelbaum (*Archives of Pediatrics,* September, 1925). The patient was an infant boy, seven months old. The meningococcus serum was recovered from the first three lumbar punctures and the paratyphoid B. bacillus from the last six fluids. It is thought that by the use of the antimeningococcic serum the meningococcic infection was brought under control but the paratyphoid infection, probably the direct cause of death, was not checked by the mixed autogenous vaccine, consisting of both meningococci and paratyphoid B. bacilli.

Congenital Transduodenal Bands.—Russell L. Haden (*American Journal of Diseases of Children,* July, 1925) studied only in the last day of life the finding of marked reduction in the blood chlorides in two cases of pernicious vomiting clinically suggestive of intestinal obstruction, as suggested by such a cause. In one case the blood carbonate was markedly increased and in the other moderately increased, indicative of alkalosis. The urine was acid and contained acetone. Both patients died during a convulsion. The nonprotein nitrogen was estimated in one case and was found markedly increased.

In both cases the duodenum presented adherent congemital bands causing traction, kinking and apparently partial obstruction. Although in most instances importance must not be placed on congemital bands, the absence of other physical findings with the occurrence of a clinical picture of partial obstruction and the blood findings of greatly reduced chlorids are suggestive of duodenal obstruction as sometimes due to this cause. In such cases it may be possible by early diagnosis to save life by operation and division of the obstructive bands, the risk being reduced by the timely therapeutic use of sodium chlorid.

The Critical Preeruptive Fever (Roseola Infantum, Exanthem Subitum).—Henry Heiman (*Archives of Pediatrics,* July, 1925) states that when the fever falls and the characteristic macular or morbilliform eruption appears, the diagnosis is obvious to one who bears the condition in mind. But the question is, "Can this disease be diagnosed before the eruption appears?" The importance of an early diagnosis lies only in the prognosis for the infection is little or not at all contagious as far as we know. Unfortunately, we have no Koplik spots as a constant forerunner and forewarner of a coming exanthem. But we have a group of cardinal symptoms which can make us strongly suspect the disease, if not lead us to a positive diagnosis. When we see an infant with high fever, perhaps of a fluctuating nature, care free and happy, with a negative physical examination or with catarrhal symptoms

of the grippe, not of a measles type, and can find enlarged glands, especially the mastoid group, then we should be on the lookout for a crisis on the fourth day of the disease with the outcrop of a morbilliform eruption. If with this suspicion in mind we do a blood examination and find a leucopenia and lymphocytosis we are justified in making a tentative diagnosis of the critical preeruptive fever. Even without a blood examination, the author has succeeded in successfully forecasting the crisis and eruption in most of his later cases, especially if other cases have called his attention to their seasonal prevalence.

Light and the Antirachitic Factor.—Bringing together clinical experiences with corresponding observations from the laboratory C. E. Bloch and Frans Faber, Copenhagen, Denmark (*American Journal of Diseases of Children,* October, 1925) in an article on the effect of light and the antirachitic factor state that light rays and particularly ultraviolet rays have a healing effect in cases of rickets and tetany and a beneficial influence in cases of anemia and diabetes through stimulation of depressed functions. They believe that the hypothetical antirachitic vitamine does not exist. Moreover, since codliver oil has the same healing action on rickets and tetany as light has, although the former, in the quantities that can be given to children, acts more slowly and less surely than light, and as this effect is not due to the vitamine A substance, there must be a stimulating factor in cod liver oil similar to that in ultraviolet light, in addition to the vitamine A substance. This, the authors continue, is easily understood since Alfred F. Hess and Steenbock, Nelson and Black have shown by animal experiments that fats and other food materials, which are without effect on rickets, can be rendered active for experimental rickets merely by exposure to ultraviolet light. Eleanor Margaret Hume and Hannah Henderson Smith (Lister Institute) have shown that exactly the same is the case with sawdust. The conclusion is that the nonspecific stimulating factor must be the ultraviolet rays.

Ketosis Accompanying Infections in Children.—Kenneth H. Tallerman (*American Journal of Diseases of Children,* October, 1925) in a study carried out on a series of children presenting ketosis associated with infection, says that in the majority of cases there appeared to be a connection with hepatic inadequacy. He adds, however, that the hepatic function may have been deranged as a result of toxemia, low food intake or overaction of the sympathetic nervous system in fever.

Blood Chemistry of the Newborn in Health and in Inanition Fever.—From data on the blood chemistry of forty-one newborn infants, eighteen of whom were suffering from inanition fever, in the first five days of life, DeWitt H. Sherman, George W. Pucher, and Harry R. Lohnes (*American Journal of Diseases of Children,* October, 1925) conclude that in inanition fever there is a marked increase of blood urea nitrogen and aminoacids together with greater acidosis as shown by the decided decrease in carbon dioxide combining power. There was, on the other hand, no decrease in the percentage water content of the blood nor was there an increased salt concentration. These socalled inanition fevers are then, it is thought, not due to increased salt concentration of the blood.

Thirst Fever in the Newborn.—Ernst Poeck (*Zentralblatt für Gynäkologie,* June 13, 1925) states that even though thirst fever is usually the rule in elevations of temperature in the newborn infant, not every instance of fever in the newborn should be considered as thirst fever. Other causes, such as pyurias, bronchopneumonias, otitis, etc., must be excluded. Thirst fever is justly called so, but the deficiency of water is the only causative factor in only a few cases. Other factors are maternal toxins, salts, and the peculiar nature of the colostric milk in the stage of transition and the associated deficiency of water. The author attributes the chief cause to the lack of fluid and the resulting exsiccation. In many cases, as in the sudden appearance of lactation—either as the result of an increase in the mother's milk or the completion of the change from colostrum—the fever recedes spontaneously. However, one should not draw the conclusion from this that the thirst fever requires no treatment. The severity of the injury cannot be estimated beforehand and it is only a short way to thirst collapse and to the comatose reaction. Therefore a sufficient administration of fluids is indicated. The feeding of water is worth while if only to shorten the febrile stage by a few hours.

Controlling Infectious Diseases in Children's Out-patient Services.—Appropriations from the Committee on Dispensary Development of the United Hospital Fund of New York rendered possible a study of methods of controlling infectious diseases in children's out-patient clinics and dispensaries, and the Pediatric Section of the Associated Out-Patient Clinics of New York aided in planning and conducting the work. Charles Hendee Smith and Michael M. Davis, Ph.D., (*Archives of Pediatrics,* October, 1925), review their findings among which are data showing that the proportion of infectious diseases in the out-patient departments of the majority of institutions approaches one per cent.

Report on the Care of Convalescent Children in Institutions.—A full report on the care of convalescent children in institutions is submitted by the Sub-Committee of the Public Health Committee of the New York Academy of Medicine (*Archives of Pediatrics,* September, 1925). Among the various measures recommended are segregation by ages and by types of disease, standards of management, personnel, regimen, length of stay, social service assistance and, lastly, a central reference bureau to lighten the burden of some of the convalescent homes and to distribute properly cases by type of condition.

Rickets and Cholesterol.—O. Rosenheim and T. A. Webster (*Lancet,* May 16, 1925) conclude: 1. That irradiation of cholesterol with ultraviolet light confers on it definite antirachitic properties, both in the presence and absence of oxygen. 2. Under the particular conditions of their experiments, increasing the time of radiation seems to increase somewhat the amount of antirachitic substance. 3. Taking the content of inorganic phosphorus in the blood as an index, it would appear that the limit of protection against rickets is reached by a dose of 0.2 mg., and this is especially marked in the half hour radiation experiments.

Immunization Against Diphtheria.—Robert A. Strong (*Archives of Pediatrics,* October, 1925) writes that we are faced with the fact that the decrease in mortality due to diphtheria and other communicable diseases has been trifling and regrets the cloud under which immunization against diphtheria has been passing in recent years. He presents the following conclusions at which he has arrived respecting the question: 1. All children should be given some protection against diphtheria, either by the production of an active immunity with toxin-antitoxin, or, 2, if they have not been so immunized, by the production of a passive immunity with antitoxin whenever they are exposed to infection by contact with an active case of diphtheria. 3. Children of the preschool age show a greater susceptibility to infection as evidenced by a very high percentage of positive Schick reactions and they may be immunized as a routine without the preliminary test. 4. Children of the preschool age are more easily immunized with toxin-antitoxin than older children and also show fewer reactions. 5. Children attending schools in the less congested sections of a city or in a rural section show, as a rule, from one hundred to two hundred per cent. more positive Schick reactions than those located in the more congested parts. 6. Repeated exposure to infection with the diphtheria bacillus is an important factor in the development of a socalled natural immunity. This is frequently seen in institution children. 7. Girls show a somewhat larger percentage of positive Schick reactions than boys. This is probably due to the fact that they are less exposed. 8. The danger of anaphylaxis is less than it was before antitoxin was concentrated and purified. Immunizing doses may be therefore given more often than when this risk was a deterring factor. 9. For the same reason, antitoxin in therapeutic doses should always be given immediately, if the slightest suspicion exists that a throat infection may be diphtheritic. 10. No child should be considered immune or protected until it shows a frankly negative Schick test and this test should not be made until approximately a year has elapsed after the administration of toxin-antitoxin. 11. A passive immunity produced by the administration of antitoxin should not be relied upon as a protective measure for a period longer than three weeks. 12. When, for any reason (asthma or known hypersusceptibility, for example), a child has not been immunized by either method it should be guarded from infection by being removed from the infected home and given the advantage of close observation. It should be cultured as often as necessary and, at the first clinical indication of infection, antitoxin in therapeutic doses given.

FRACTURES

Theory and Treatment of Spiral Fractures.—E. Rixford (*Annals of Surgery,* January, 1925) recommends the following technic: The limb is thoroughly washed with ether, rubbing well with gauze pad and using enough ether, then with alcohol seventy per cent., then painting with picric acid five per cent. in seventy per cent. alcohol. If grain alcohol is used in making the picric acid solution dermatitis is practically avoided. Formaline alcohol should not be used for that will blister. I have seen but one case in more than a thousand where the use of picric acid in grain alcohol has been followed by a popular dermatitis.

A longitudinal incision is made over the spiral portion of the fracture which may readily be determined by the x ray, but on the tibia, as said above, the spiral portion is always in front, which is fortunate, for the incision can be made over the flat anteromedian surface of the bone.

The bone is exposed, but care is taken not to strip up the periosteum, and blood clots, which cover the medulla and the edges of the bone, are carefully preserved *in situ.* Loose chips of bone which lie between the fragments are removed. The fragments are drilled at points which will be opposite each other when the fracture shall have been reduced. A stout wire of annealed silver is threaded through the drill holes, the fracture reduced by traction and prying and pulling with hooks, care being taken not to break off the long tips of the fragments lifting out shreds of periosteum which may lie over the edges of the bone; the wire is drawn taut and twisted and the twisted ends hammered down against the bone out of the way. The wound is closed and the limb put up in some external retentive appliance, a suspension apparatus, Thomas splint or plaster of Paris cast. If plaster of Paris is used, complete fixation of joints above and below should be secured in order to prevent rotatory deformity. The plaster case should be removed in ten or twelve days, the stitches removed, the limb massaged, and the joints moved. One advantage of the use of suspension apparatus over that of plaster is that it permits massage and electrical stimulation of the muscles as with a weak faradic current by which muscle tone is maintained and a greater derivation of blood to the limb is brought about, thereby favoring caluus formation and rapid union.

Fractures of Neck of Femur.—R. Whitman (*Annals of Surgery,* January, 1925) concludes from a series of cases that the abduction treatment, because it is comprehensive in its scope and equally effective for every type of fracture, has raised the most neglected of all fractures to the first place in the therapeutic scale. At the present time the opposition to the general adoption of the abduction treatment is rather of the nature of inertia than of loyalty to the ancient ritual, the chief objection being, apparently, that its application, particularly the adjustment of a secure and comfortable blaster spica, requires more skill and experience than is possessed by the average worker. This proposition, in effect, that incompetence should disqualify the treatment rather than the surgeon, however logical under the old dispensation, is no longer tenable. For traditional authority having been disproved and discredited can no longer assure immunity for inadequacy, inefficiency and neglect.

Fractures of Femur.—H. E. Conwell (*Surgery, Gynecology and Obstetrics,* January, 1925) summarizes his study of cases as follows:

1. Fractures demand great care and judgment on the part of those with competent surgical training.
2. Proper splinting, combating shock, and immediate reduction should be done.
3. All fractured femurs should be hospitalized and treated as a major surgical case.
4. Anteroposterior and lateral röntgen rays should be made, and the type of fracture, muscle pull, and condition of patient should be very carefully studied.
5. An anesthetic should be given in every case if the general condition permits.
6. Treatment with skeletal traction, knee flexion and suspension, with the modification of the Balkan-Blake frame was found very efficient.
7. Frequent checks with the röntgen ray, daily treatment with radiant light, diathermy, massage, and active and passive motion should be carried out from the date of injury until final discharge.
8. The limb should be removed from the splint as soon as enough callus has formed to prevent malposition, and placed in supportive splints, which can be easily removed for daily inspection and treatment of limb.
9. All supportive splints should be removed as soon as possible, and weight bearing allow with the aid of crutches as soon as röntgen ray and physical examination show enough callus formation.
10. Compound fractures should have a thorough débridement, closure of the wound, administration of antitetanus serum; otherwise treatment is the same as for the simple fracture.
11. Circular plaster casts should not be applied.
12. Open reduction should always be avoided until a fair trial with skeletal traction and suspension has been carried out.

Treatment of Wounds in Long Bone Fractures.—F. Beekman (*Surgery, Gynecology and Obstetrics,* January, 1925) draws the following conclusions:

1. The wounds of compound fractures can be roughly divided into two groups, those produced from within out and those from without in.
2. Wounds produced from without in are more apt to be contaminated, and the damage to the various tissues is greater than those produced from within out. Consequently, there is greater possibility of infection following such a wound.
3. No standard type of treatment can be used for the wounds of all compound fractures.
4. The indications for treatment of compound fractures are reduction of the fragments with as little trauma as possible, removal of contaminated and devitalized tissue, the elimination of dead space and the prevention of infection spreading into the wound from the surface.
5. In the simpler types, cleansing of the skin, sterile dressing and immobilization is sufficient. In those with more severe wounds, the above conditions can be brought about best by immediate reduction of the fracture, thorough cleansing and débridement of the wound, obliteration of dead space by means of traction and prevention of surface infection by Carrel-Dakin treatment.
6. In those cases in which infection has been prevented and in which it has bleen possible to cover the bone with soft parts, union at times takes place as in simple fractures.

Fracture Inconsistencies.—F. H. Albee and G. Anopol (*International Journal of Medicine and Surgery,* March, 1925) favor the use of tailor made splints in the form of plaster of Paris, rather than custom made splints in the form of many of the braces frequently employed today. The ignorance of proper plaster of Paris technic accounts for its not being more generally used. Once mastered, it is one of the most important elements of the bone surgeon's armamentarium. As a postoperative dressing, it acts as an efficient hemostatic. This is brought about by proper molding before the plaster is allowed to fully harden.

As regards terminal swelling the limb should be elevated before swelling takes place and not afterward. The wound dressing should never be held in place by a rigid encircling bandage, but by means of the plaster cotton or whatever material is used to protect the limb when applying the plaster, for the reason that the encircling bandage with soft compressible cotton on either side may act as a tourniquet in the event of swelling of the limb.

Fractures of the Neck of the Femur.—R. G. Carothers (*International Journal of Medicine and Surgery,* May, 1925) says that there is no treatment yet devised which will save all these people and give them perfect limbs, but we believe the Whitman spica most nearly fulfills the requirements in these cases and is the most comfortable to the patient and the easiest in which to nurse him. Our results have improved considerably with the increase in skill which we have acquired in putting on these spicas, so that we now believe that our greatest difficulty with these cases lies after the third month. The active patients want to walk early; we have had them do this and refracture their hips or severely strain the union and cause more shortening. The older people sometimes require a great deal of urging before they will use the leg even when it is safer to do so, but these difficulties will arise no matter what treatment is instituted, and can only be handled by a closer personal touch with each individual case. When it is possible to keep the patient in a hospital or where his home is conveniently enough located, so that physical therapy, such as baking, massage and diathermy, may be carried out, these difficulties are reduced until they are almost nil.

Medicolegal Notes.

HOSPITAL RECORDS AS EVIDENCE

The Michigan Supreme Court holds, Metropolitan Life Ins. Co. v. Dabridka, 232 Mich. 36, 204 N. W. 771, that, there being no state statute permitting hospital records to be used as original evidence, such records were not admissible where the witnesses who testified that they were records of the case had no personal knowledge relative to them, and there was no proof that the person who made them, or the doctor or other person who directed the entries to be made, might not have been produced as a witness, or that the records were made in the ordinary course of the business conducted by the hospital by a person whose duty it was to make them.

HYPOTHETICAL QUESTIONS AS TO TESTAMENTARY CAPACITY

The Minnesota Supreme Court holds, In re Weber's Estate, 204 N. W. 52, that the opinion of medical experts on the testamentary capacity of a testator is admissible in a will case to aid the jury, and a hypothetical question to obtain such opinion "may be framed upon as favorable a view of the facts as the testimony for the party propounding the question may warrant. If not so framed, the objector should call attention to facts omitted or overstated, for it is difficult for the court as well as opposing counsel to have all the testimony in mind."

POSSESSION OF NARCOTICS UNLAWFULLY ACQUIRED AN OFFENSE

The Washington Supreme Court holds, State v. Radford 236 Pac. 804, that the state drug act, Laws 1923, p. 133, §3 et seq. make the following acts criminal: 1, To sell, furnish, or dispose of such drugs; 2, to have in possession such drugs unless they were lawfully required; 3, to have them in possession unless lawfully obtained. The defendant was charged under the last classification with being in possession of drugs which he had unlawfully acquired. It is held that it is not necessary in order to convict a person who had unlawfully obtained drugs and had them in his possession, that it must further appear that he intended to sell, furnish or dispose of them.

PROOF OF REASONABLE VALUE OF PHYSICIAN'S SERVICES

In an action by a physician for compensation for his services, the Arizona Supreme Court held, Maryland Casualty Co. v. Sweek, 236 Pac. 720, that it was error to admit the testimony of another physician as to what he charged for similar operations, since reasonable value is proved by the general customary charges for similar services, and not by what some particular person charges, and the witness stated he did not know the general custom.

The plaintiff alleged a promise to pay the reasonable value of his services, which he alleged to be $474. The defendants alleged a definite agreement to perform the operation for $150. The jury, on conflicting evidence, found there was no agreement as to the price, and returned a verdict of $400 in favor of defendant. Since none of the witnesses fixed the value of the services at less than the amount of the verdict, while some of them were considerably higher, it was held that the erroneous admission of the physician's testimony as to his charges was not reversible error.

LIMITED AND FULL SANIPRACTIC LICENSES IN WASHINGTON

The Washington Supreme Court holds that a license to practice is not a contract, but the right to practise is a valuable property right. It also holds, State v. Maybury, 236 Pac. 566, that where a sanipractic who had a limited license to practice drugless healing applied for and was granted a full sanipractic license, when he was required to surrender his limited license, and the full license was afterwards revoked under Laws of Washington 1925, c. 10, providing for revocation after a hearing before the license department as to whether the qualification on which the full license was issued had been properly secured, the sanipractor was entitled to the return of his limited license, his failure to be entitled to the full license being caused by lack of additional qualifications, which did not affect his right to a limited license.

REGISTRATION OF HOSPITAL NURSES

The New Jersey Supreme Court holds, Castellini v. New Jersey State Board of Examiners of Nurses, 128 Atl. 544, that a graduate of a hospital nursing school who is eligible for registration without examination on application within two years after the passage of P. L. 1923, p. 261, §6, cannot be denied registration because the hospital has a daily average of less than fifty patients, that being the requirement under §5, for nurses who must undergo examination before being eligible for registration.

DEGREE OF CARE AND SKILL REQUIRED

The New Jersey Court of Errors and Appeals holds, Lolli v. Gray, 128 Atl. 256, where the chief question was the advisability of protecting the bandages on an injured leg from infection by means of a rubber cloth, that a physician and surgeon, in the absence of express contract, is only required to exercise the skill and care ordinarily possessed and exercised by others in the profession; and a judgment for plaintiff was reversed for a new trial.

TOOL GRINDER'S CONSUMPTION HELD COMPENSABLE

Under section 11 of the Connecticut Workmen's Compensation Act, "injury" includes any disease due to causes peculiar to the occupation and which is not of a contagious, communicable or mental nature. Where a claimant's work as a tool grinder injured him by producing a condition of the lungs which offered weakened resistance to either staphylococcus infection, or streptococcus infection, or infection from the tubercle bacilli, the Connecticut Supreme Court of Errors held, Kovaliski v. Collins Co., 128 Atl. 288, that the injury was the condition of weakened existence to infection, whether that condition has a distinctive name, as pneumoconiosis, or not, and when that condition of weakened resistance yields to infection and makes the workmen unfit to work, the injury has become compensable.

It was also held that the fact that grinder's consumption, resulting from infection by the tubercle bacilli, is communicable, did not bar recovery under section 11, it being the weakened resistance to infection which is the injury compensated for, which weakened resistance is not contagious nor communicable.

SPECIALISTS' FEE INCLUDED IN MEDICAL AID

In a proceeding for compensation for lacerated wounds on the face affecting the right eye, the claimant asked the medical services of a specialist in addition to the first aid by a local physician, allowed by the Commission. The Minnesota Supreme Court, Baker v. Rundquist, 203 N. W. 452, held that he was entitled to the additional services. The court said: "The physician giving the first aid treatment was not a specialist and gave treatment only for the superficial wounds. The specialist gave treatment and he thought it was needed. The workman was entitled to exploratory treatment, and perhaps to all that he received."

Observations from a Clinical Study of 401 Patients with Cardiovalvular Defects*

DAVID PERLA, M.D.

New York

In this paper there is no attempt at a complete statistical analysis of the 401 cases from which the material is drawn. There are, however, certain features of sufficient interest and importance to warrant emphasis. Exhaustive statistical studies on valvular heart disease have been published, the substance of which is repeatedly mentioned in standard works on the subject. But there is a surprising lack of critical analysis in many of these papers. As a result of these studies, our prognostic standards in heart disease were a little distorted until Mackenzie and others established a saner cardiac philosophy. Although in this paper I discuss valvular defects, it is understood that these defects do not constitute a disease per se; that, as the French say, *"Une maladie des valvules n'est pas une maladie du coeur."* But for academic reasons, we still speak of chronic cardiovalvular disease.

During 1922 to 1924 inclusive, there were 401 cases of chronic cardiovalvular disease discharged from the Montefiore Hospital; of these sixteen or 3.9 per cent. were attributable to syphilitic infection, 199 or 49.8 per cent. to rheumatic infections and in 186 or 46.3 per cent. the exact etiological factors could not be determined. The criteria for classifying a case as rheumatic are, 1, a positive history of rheumatic infection, 2, absence of a positive Wassermann or a history of lues, and 3, absence of arteriosclerosis.

In analyzing the cases of heart disease in Montefiore Hospital from 1914 to 1921 inclusive, and 1922 to 1924 inclusive, we find

	Boas 1914-1921	*Perla* 1922-1924
Patients with valvular disease	536	401
	Per cent.	*Per cent.*
Pure aortic insufficiency	6.3	3.7
Combined mitral and aortic disease	20.9	24.4
Mitral disease	72.8	71.9
Patients with aortic insufficiency alone or combined with other lesions	146	113
	Per cent.	*Per cent.*
Rheumatic	77.4	47.9
Syphilitic	7.2	14.1
Arteriosclerotic	14.4	0.0
Undetermined (including arteriosclerosis)	0.0	38.0

The number of the various valvular defects is quite comparable to the figures in the collected tables of Jürgensen. (1) Uncomplicated mitral lesions comprise more than sixty per cent. of all valvular defects; uncomplicated aortic lesions, however, only about three per cent.

1. SYPHILIS

The low percentage of luetic cases is striking and indicates that this type of cardiac disease is uncommon among the Jews. Boas (2) found the incidence of positive Wassermann reactions in a series of 559 Jewish patients to be 6.2 per cent. for males and 2.4 per cent. for females. This must be considered in evaluating the significance of the frequency of syphilis as a cause of valvular disease. The sixteen cases all presented signs of aortic insufficiency. In the total series, aortic insufficiency was present 113 times. Of these 14.1 per cent. were luetic, forty-three or thirty-eight per cent. were arteriosclerotic or of undetermined etiology and fifty-four or 47.9 per cent. were rheumatic. This is in striking contrast to the findings of other observers. Hubert (3) in Romberg's clinic found that of the cases of aortic insufficiency sixty-seven per cent. were syphilitic, seventeen per cent. rheumatic, 5.5 per cent. arteriosclerotic. Of 182 cases of aortic insufficiency which Longcope (4) collected from the literature, 74.1 per

Copyright, 1926, by A. R. Elliott Publishing Company.

cent. were luetic. Broomhead (5) found 58.7 per cent. of 121 cases of aortic insufficiency syphilitic, 41.3 per cent. rheumatic. Boas in studying the 536 cases of valvular heart disease admitted to Montefiore Hospital during the period of 1914 to 1921 found 77.4 per cent. rheumatic, 14.4 per cent. arteriosclerotic and 8.2 per cent. luetic.

Ormbarg (6) found in a large clinic in Christiania, Norway that of a series of 577 cases only 8.1 per cent. were definitely syphilitic, although of 314 cases 14.3 per cent. gave a history of syphilis. Although higher than the figures of Boas or of the present series, it is strikingly low in contrast to what other observers have found. Since syphilitic heart disease is often of short duration after the appearance of symptoms, the patient may not live long enough to reach a hospital for chronic diseases. He is ambulatory for some time; dissolution frequently occurs within a few months after the onset of severe symptoms and the patient dies in the general hospital. Nevertheless, I am inclined to agree with Boas that the incidence of syphilis as a cause of valvular disease (generally aortic) is overestimated.

2. UNDETERMINED GROUP

After a careful analysis of the cases included in the arteriosclerotic group, it was found that a diagnosis of arteriosclerosis of a heart valve was generally made on insufficient evidence, that often the age of the patient or the presence of peripheral arteriosclerosis was sufficient to term a concomitant cardiac murmur as arteriosclerotic in origin. When one considers the relative infrequency of actual pathological deformation of the mitral valve, it is evident that too often a relative mitral insufficiency due to a dilatation of the orifice is clinically attributed to arteriosclerotic valvular disease. Of course in a frank case of diffuse arteriosclerosis where x ray reveals calcification of the aorta, it is presumptive evidence that the etiological factor in a concomitant valvular disease is arteriosclerosis (where no autopsy is obtainable). Many of the so-called arteriosclerotic cases are obviously therefore not entirely or in part of arteriosclerotic origin. Anitschkow believes that an old healed rheumatic valvular lesion may thoroughly simulate an arteriosclerotic process. Boas and I (7) have pointed out that arteriosclerosis of the mitral ring is a characteristic pathologic finding in arteriosclerotic mitral stenosis. However, a large number of mitral stenoses in the later periods of life, even in the presence of general arteriosclerosis may be of ancient rheumatic origin. It is highly probable that minute rheumatic valvular lesions may form the nucleus for a later arteriosclerotic change, the avascularity encouraging sclerosis. This has been more fully discussed in another paper. The percentage of arteriosclerotic defects is high of course in any series that includes so great a number of older people.

Ormbarg found arteriosclerosis the etiological factor in 7.8 per cent. of all the valvular defects in his series—Eishhard (8) in 12.5 per cent., Stintzing (9) in fifteen per cent., Mengel (10) in twelve per cent., Gerhardt (11) in nine per cent., and Admuhler (12) in only 3.7 per cent. In the series under discussion, I was unable to arrive at a definite estimate of the exact number of cases that are due to arteriosclerosis, though the case records show over forty per cent. After deducting those due to a relative mitral insufficiency and those on a probable rheumatic basis, probably less than twenty per cent. are definitely arteriosclerotic. However, I have placed these with all the doubtful cases in the undetermined group. Aortic insufficiency comprised twenty-three per cent. of the undetermined group while sixty-one per cent. had mitral insufficiency and sixteen per cent. mitral stenosis.

3. RHEUMATIC GROUP

The rheumatic group affords considerable interest. We are dealing with a relatively older group than is found in the general hospital. The age groups in the table below reveal the striking facts that fifty-three per cent. were in adults over thirty, thirty-four per cent. over forty, and seventeen per cent. over fifty. In part, this is accounted for by the fact that our cases are of the older groups. To speak therefore, of rheumatic valvular disease as a disease of youth and early adult life is to overlook a large group of cases that survive unnoticed and untroubled until late in life.

RHEUMATIC HISTORY

Many of these cases, however, developed their infection early in life. A history of acute articular rheumatism was given in thirty-nine per cent. of the cases, of chorea in nine per cent., of tonsilitis in twenty-five per cent. giving a total of 112 or fifty-six per cent. of all C. R. C. V. D. cases with a positive rheumatic history.

TABLE II

Age Groups in C. R. C. V. D. Cases at Time of Admission to Hospital

Ages	*Males*	*Per cent*	*Females*	*Per cent*	*Total of Each Gr.*	*Per cent of total No. of cases*
1-10	10	5	4	2	14	7
11-20	31	16	30	15	61	31
21-30	7	3	12	6	19	9
31-40	18	9	19	9	37	19
41-50	13	7	21	11	34	17
51-60	9	4	23	12	32	16
61-70	0	0	2	1	2	1
Total	88	44	111	56	199	100

The most frequent valvular disease of this group was mitral stenosis. There were 147 or seventy-four per cent. cases of mitral stenosis with and without other valvular defects. It is interesting that in six of these there was a complicating hypertension.

TABLE 3. C. R. C. V. D.

		Percent
Mitral stenosis	147	
With mitral insufficiency	139	94
With aortic insufficiency	44	31
With aortic stenosis	6	4
With tricuspid lesions	9	6
With pulmonary insufficiency	2	1
With hypertension	6	4
With atherosclerosis of pulmonary vessels	1	7
With subacute bact. endocarditis	1	7

The presence of a presystolic murmur in cases of hypertension with enlargement of the left ventricle may be due to a relative mitral stenosis and not to an organic valvular defect. In the presence of hypertension, the diagnosis of organic mitral stenosis must be made with caution.

TABLE 4. C. R. C. V. D.

	No. cases	*Per cent*
Aortic insufficiency	64	
With mitral insufficiency	56	87
With mitral stenosis	50	78
With aortic stenosis	18	28
With tricuspid insufficiency	2	3
With tricuspid stenosis	2	3
With hypertension	7	10

PALPABLE SPLEEN

It is generally believed that the spleen is not enlarged in chronic rheumatic-valvular infections in

the absence of subacute bacterial endocarditis or of infarction. J. E. Talley and W. H. Lindsey (13) report palpable spleens in three per cent. of 198 adults and in six per cent. of eighty-eight children with chronic valvular disease. They attribute it to chronic passive congestion. J. H. Arnett (14) found the spleen often enlarged in patients who had died in acute or recurring endocarditis, and the enlargement was independent of any liver enlargement. He attributes this entirely to infection.

In our series of 199 cases of chronic rheumatic valvular disease, twenty-four had a palpable spleen. About twelve per cent. of each of the age groups, one-ten, eleven-twenty and twenty-one and over, had a palpable spleen. Of the twenty-four cases, ten cases had auricular fibrillation at the time of examination. Malaria and other causes of splenomegaly were ruled out. A few occurred secondary to infarction in cases of fibrillation of the auricles. Only three of the cases, however, with a clinically palpable spleen came to autopsy. Of these two were not above the normal weight. The third, a man of fifty-six with a mitral stenosis of rheumatic origin complicated by a general arteriosclerosis with a moderate cirrhosis of the liver and a myocardial failure with a diffuse anasarca had a large firm spleen. The capsule was thick, the malpighian bodies appeared of average size, but microscopically the sections showed peculiar germinal centers outside the vessel walls in the malpighian germinal follicles. There was an accumulation of epitheliod like monocytes and recent large lymphocytes in a loose stroma of fibrillar connective tissue. The rest of the malpighian corpuscle was normal. There was a moderate congestion in the spleen. I do not believe the splenic enlargement was dependent on the cirrhosis of the liver. Nevertheless, a palpable spleen can be demonstrated clinically with considerable frequency in valvular disease in the presence of chronic rheumatic infection. Its pathogenesis is unknown.

Relation of fever to decompensation in chronic rheumatic cardiovalvular disease.

In reviewing the cases of myocardial insufficiency, it was found that in thirty-five cases of chronic rheumatic cardio-valvular disease with marked evidence of myocardial failure, sixty per cent. had a subnormal temperature during the period of decompensation; twenty-one per cent. had a temperature that stayed within normal limits; and twenty per cent. had slight irregular fever. The occurrence of infarcts and of secondary intercurrent acute infections as broncho pneumonia was, of course, not included. In the presence of circulatory failure, it is to be expected that the temperature of less vital structures is lower than normal. It is lowest in the early morning hours. The impairment of the ventricular output results in the failure of the circulation to maintain uniform normal temperature in the peripheral parts of the body.

4. CARDIAC IRREGULARITIES

The frequency of cardiac irregularities is greater in this series because of the marked extent of myocardial damage prevalent in many of our cases. Auricular fibrillation occurred in 112 or twenty-nine per cent. of the cases. Of these seventy-eight per cent. were in the rheumatic group, twenty per cent. in the undetermined group, one and five tenths per cent. in the syphilitic group. Fifty-seven per cent. of all cases of auricular fibrillation occurred in mitral stenosis.

TABLE 5. CARDIAC IRREGULARITIES

		Per cent.
Total C. C. V. D. cases	401	
Paroxysmal tachycardia	3	.8
Auricular fibrillation	112	29.
Heart block	6	1.5
Bundle branch block	3	.8
Arborization block	5	1.
Auricular flutter	3	.8

TABLE 6. AURICULAR FIBRILLATION

Etiology of Valvular Disease	*Total Cases*	*Auricular Number*	*Fibrillation Per cent.*
Rheumatic	199	88	44.2
Syphilitic	16	2	12.5
Undetermined (including arteriosclerosis)	186	22	11.8
Total	401	112	29.0

5. PROGNOSIS IN C. R. C. V. D.

The prognosis in the rheumatic group is better than is generally believed. Thormeyer (15) compiled statistics on 122 cases of heart disease with the exact history and necropsy findings. The average time of compensation was over thirty-three and one half years when the rheumatic infection had been acquired between the ages of one and twenty years. It was fourteen and one half years in patients with the rheumatic infection acquired between twenty-one and thirty, and only five and six tenths years if they had acquired it between thirty-one and forty. The average interval between the first and second phases of decompensation was four years in mitral insufficiency and about eight months in aortic insufficiency. This, however, is a selected series, for those who died early in life are manifestly omitted. In general we have found that if myocardial insufficiency occurs before puberity, the outlook is poor, although we have one case that has been more or less continuously decompensated for fourteen years. If, however, the patient survives the adolescent period without myocardial failure, the outlook is much brighter.

The prognosis in valvular defects depends, of course, on 1, the presence of infection; 2, the condition of the myocardium; 3, the presence of irregularities, particularly auricular fibrillation; and 4, the degree of physical activity of the patient. The severity of the valvular lesion is of lesser importance. Twenty-five per cent. of the 199 rheumatic heart patients died under observation. Of these, thirty-seven per cent. were under twenty, thirty per cent. between thirty and fifty, and twenty-three per cent. over fifty. Mitral stenosis alone or with other valvular defects was present in forty-four of the forty-eight fatal cases.

TABLE 7. AGE AT DEATH IN C. R. C. V. D.

Age	*M.I.*	*M.S.&I.*	*A.I.*	*A.S.*	*M.&A.*	*M.S. T.I.*	*M.S.A. I.T.I.*	*Total*
1-10	..	2	..	..	3	..	..	5
11-20	1	6	..	..	3	3	..	13
21-30	..	2	..	..	1	..	1	4
31-40	..	5	..	..	2	1	..	8
41-50	2	1	..	..	5	..	..	8
51-60	..	6	..	..	2	2	..	10
								48

No patient with pure aortic disease died under observation. In fifty per cent. of the cases that died, the auricles were fibrillating.

The duration of the disease in the rheumatic group was difficult to estimate. In those cases in whom the onset was apparently between one and ten, the average duration of life from the time of onset of heart disease to death was 11.8 years, although it varied from one to thirty-six years. In the eleven to twenty group, the range was from two to twenty-eight years, the average being 9.1 years; in the twenty-one to thirty group, the range was from six to fifteen years, the average being 8.6 years; in the thirty-one to forty group, the average was 9.1 years; forty-one to fifty group, 8.1 years, and the fifty-one to sixty group, 4.6 years. The following table indicates the duration of life in these cases. Many deaths were not due to cardiac failure but to an intercurrent infection.

TABLE 8. DURATION OF LIFE AFTER ONSET

Age of Onset	*No. cases*	*Range of Duration Years*	*Average Duration Years*	*Remarks*
1-10	5	1-36	11.8	1 died of bronchial pneumonia 1 died of acute bacterial endocarditis 1 died of subacute bacterial endocarditis 1 died of lobar pneumonia
11-20	13	2-28	9.1	1 died of uremia 1 died of lobar pneumonia
21-30	14	6-15	8.6	1 died of acute bacterial endocarditis
31-40	8	3-20	9.1	
41-50	8	3-15	8.1	
51-60	10	4-5	4.5	

It is interesting however to note that among those still alive, nine patients in whom the disease commenced under twenty had had the valvular defect twenty years or more at time of discharge.

Mackenzie has seen many patients with mitral stenosis reach extreme old age without symptoms. In our series of fifty cases of mitral stenosis in adults over fifty years, many had had no symptoms although many undoubtedly had had the valvular defect since childhood. As is evidenced by this study and as has long been known, it is the state of the cardiac muscle which determines survival and activity.

CONCLUSIONS

1. The incidence of syphilis as a cause of valvular disease (generally aortic) is overestimated.

2. Mitral stenosis in patients over fifty years of age is not uncommon. Clinically it is often difficult to determine the etiology of valvular defects in older patients.

3. In the rheumatic group, fifty-three per cent. were in adults over thirty, seventeen per cent. in adults over fifty. Fifty-seven per cent. of the patients with chronic rheumatic cardiovalvular disease gave a positive history of rheumatic infection. The most frequent valvular defect of this group is mitral stenosis.

4. A palpable spleen in chronic rheumatic cardiovalvular disease in the absence of infarction and subacute bacterial endocarditis is not uncommon. It was found in twelve per cent. of our cases.

5. In the presence of myocardial insufficiency, in the absence of secondary infection or infarcts, the temperature is generally subnormal.

6. Auricular fibrillation occurs more frequently with mitral stenosis than with other lesions, and in rheumatic cases more frequently than in the other groups.

7. The prognosis of cardiovalvular disease depends on 1, presence or absence of infection; 2, state of the myocardium; 3, the presence or absence of auricular fibrillation, and 4, the degree of physical activity of the patient. The duration of life from the time of onset is longest if the disease is acquired under twenty, provided the patient survives early reinfection. In general, the prognosis in well compensated cases is far brighter than is generally believed. Many reach old age with their valvular defects. A defect of the valves is not disease of the heart.

The author's references will appear in his reprints.

European School Hygiene and Other Notes

EDWARD A. TRACY, M.D.
Boston

In modern social life the school hygiene service holds an important place in big cities. Its aim is to increase the health of the school children. It does this principally by a periodical examination of each child, thus finding the unhealthy ones. The parents of these are advised of the means for health improvement. Also an unceasing watch is kept up for the contagious diseases. Children with these diseases are immediately excluded from school and thus much ill health is prevented.

The school hygiene service consists of teachers, school nurses and school doctors all working together for a single aim, the health of the school child. Their work is rendered effective by the essential cooperation of the parents, easily obtained as a rule, for every parent seeks the welfare of its child. While the principles upon which school hygiene are based are quite the same in all large cities, there are variations in the methods employed in getting results that merit investigation. Indeed we may consider school hygiene service as a phase of social progress that is in the evolutive stage. This makes a study of the school hygiene services in various countries interesting and instructive.

While in Europe during the past summer, I had the privilege of examining the school hygiene service in Frankfort, Vienna, Paris, and London, with an eye in particular for observing the care given to the problem of epilepsy in school children.

Dr. Schlosser, the Health Commissioner of Frankfort, is also Director of School Hygiene. I visited him in the Rathaus, after my desire to examine this department had been made known to him by Dr. Groebel, the eminent heart specialist of Bad Nauheim. I told Dr. Schlosser that I was especially interested in the care given to epileptic school children. I learned through him that there are about 50,000 children in the public schools of Frankfort. Their

health is looked after by fifteen school doctors, and three specialists; otologist, ophthalmologist, and neurologist. The latter diagnoses the cases of epilepsy among the school children, by observation and the history of the case. He also determines which children shall be placed in the mentally backward classes, each of which consists of fifteen to twenty children. There are three schools occupied by these mentally backward children, each school having about three hundred. Every school is visited twice a week by the school doctor. The children are examined upon their entrance to school life, in their fifth year in the schools and again in their last year of school. Dr. Schlosser gave me this information through Miss Gross, the special nurse connected with the health department, who served as interpreter, and he then kindly directed her to assist me in every way to gain a knowledge of the service. She presented me with a set of the forms used by the doctors and teachers in their school hygiene service, and explained in detail their use.

A unique feature of this service that appealed especially to me, is that at the psychiatry clinic of the University (it will be remembered that the Frankfort University is the seat of learning where Professor Ehrlich taught) and situated within the city limits, there are twenty-five beds set aside for cases of chronic epilepsy and other mental disease in school children. These children have a school room and a special teacher, and a playground. The pleasant doctor in charge, a young woman, showed me several patients with chronic epilepsy and a case of encephalitis lethargica. Miss Gross informed me that this special school with hospital care for these cases had been established more than four years. This shows that Frankfort is on the advance line in school hygiene; and a similar provision for such unfortunate children might well be established in our own city. Another feature of the hygiene service in Frankfort is the care taken to prevent tuberculosis and deformities from wrecking the lives of school children. There are six stations where sun and air baths are given to children certified by the school doctors; and children who need treatment for spinal curvature, round shoulders, etc., are sent likewise certified to the orthopedic clinic. Also, as a preventative measure, a provision is made that poor families can get sufficient milk for school children at half price, the town paying the difference.

VIENNA

In Vienna, the school hygiene service is under the direction of the health commissioner, Dr. Boehm, a fine large, big hearted man, whose characteristics reminded me very much of our Boston health commissioner Dr. Mahoney. I was introduced to Dr. Boehm by the genial Dr. Foramitti of the health department, who had visited Boston a few months previously. Dr. Boehm told me that in 1910 Vienna had a population of 2,100,000; now it is 1,860,000. The number of children in the city's five hundred schools is now 150,000, while before the war their number was 242,000. There are seven full time school doctors, and thirty-five part time. All are under one central inspector in Dr. Boehm's office. The number of nurses is 169, for the schools' and child health service. Each part time doctor visits eleven to twelve schools, contining in all 2,000 to 4,000 pupils; and each full time doctor has twelve to sixteen schools in his charge, containing 3,900 to 5,000 children. The schools are visited once a week. The full time doctors carry out the health service in the kindergartens also. There are three specialists connected with the Board of Health, eye, ear, and orthopedic. The school doctor refers such pupils as he deems desirable to these specialists. The specialist certifies to the condition found present and writes on the certificate what he deems advisable for each child examined. The hospitals and clinics of Vienna are world famous, being in charge of men devoted to medical research. One of these is the von Pirquet Children's Hospital. I visited it hoping to meet Professor von Pirquet; but he was absent on a brief vacation, and his first assistant, Dr. Noble, graciously received me and invited me to make the rounds of the hospital with him and his post graduate men. On my expressing a desire to demonstrate the objective signs of epilepsy, the white spots and epileptic skin reactions, he said there was in one of the wards a luetic girl that had convulsions that might serve my purpose. Dr. Noble then commenced his visit to the wards which I shall briefly describe. First there was the exanthemata ward. This was glassed in, so that in passing through a corridor the students could study the patients without the danger of spreading infection. Before entering the infants' wards, all of us had to don a long white garment, since, it was explained to us, infants were particularly susceptible to infections. The open air ward, on a roof, gave a wonderful demonstration of tubercular children well tanned and nourished, all on the road to complete restoration to health. They were doing their calisthenics when we visited them. In another ward were children very sick with lung diseases. In some cases immobilization of the lung by nitrogen gas is employed, the method first employed by our brilliant American surgeon, the late John B. Murphy. When we reached the bed occupied by the luetic girl, Dr. Noble invited me to demonstrate my findings in epilepsy and vasomotor tester. The epileptic skin reactions were found present. Mr. MacKahnn of the Boston Children's Hospital was present, also a guest of Dr. Noble. Afterwards I visited Dr. Lazar and Dr. Theresa Bettleheim Stein in the out patient department. They were much interested in the work done in the Boston Forsyth clinic in diagnosing and curing epilepsy in children, and in the photographs of the white spots of epilepsy taken at the Forsyth.

I had told Dr. Foramitti that I desired to meet University Professor Josef Wiesel, whose research work on status lymphaticus is known among medical men the world over. I was delighted, therefore, to receive an appointment to meet Professor Wiesel at the Franz Josef Spital, where he teaches internal medicine. Wiesel is a handsome man, with bushy black hair and a magnificent profile. In his work on status lymphaticus he showed that there is always present a hypoplasia of the chromaffin tissue in the body. It is the chromaffin tissue that furnishes adrenalin to the blood, and to lack of it Wiesel attributes the sudden death. I reported to Professor Wiesel that I had written a paper some six or seven years ago on the Mechanism of Death in Status Lymphaticus, in which it was shown from experimentation on the vasoconstriction reflex that this death was due

to insufficient adrenalin in the blood stream; but that I had refrained from publishing the paper because I was not assured of the condition of the heart in this death, whether the heart was in diastole or not. Professor Wiesel told me it is "invariably in diastole"; as this caps with conviction the conclusion reached in the paper, I shall shortly publish it. Later in the day, on meeting my fellow townsman, Dr. MacKahnn, I told him of my conversation with Professor Wiesel; and apropos of the subject MacKahnn said: "A year ago I treated a child with status lymphaticus, in collapse at operation. I injected three minims of adrenalin solution into its heart chamber. The child is alive today."

Insufficiency of adrenalin in the blood stream I believe can be easily determined by the use of my vasomotor tester; the tester is drawn over the skin of the cheeks and forearms, and if there is no resultant reflex, or if it is weak, there is insufficient adrenalin in the blood stream. In such a case a subcutaneous injection of adrenalin should be given before an operation. This reference to status lymphaticus is quite a digression but the importance of the subject warrants it.

PARIS

On my arrival in Paris a gentleman gave me a letter to Dr. Contet, Medical Inspector of the Schools. He explained to me the working of the school hygiene system and gave me letters of introduction to the Secretary of School Administration (where I obtained copies of the forms used in the service) and to Dr. G. Paul-Boncour, the neurologist in charge of the abnormal children in the Paris schools. By his writings and efforts the detection of early cases of epilepsy in the schools has progressed more than elsewhere in Europe. A reprint of a talk which I gave to the Boston school nurses in 1919 met with his hearty approval, based on his similar work and experience in the schools of Paris. In his book, *Les Anomalies Mentales chez Les Ecoliers,* are passages that could well be reprinted for the enlightenment of school doctors and school teachers everywhere.

Special attention is also given in the Paris schools to the pretuberculous children, and this is reflected in the forms used in the hygiene service, calling for radiographic investigation of the child's chest in a suspected case. I had hoped while in Paris to pay my respects to Professor Sergent, the eminent clinician at the Charitè, but he was *en vacances;* Dr. Paul Bordet, Chef de Clinique, gave me a card to Dr. Alajouanine, neurologist at the Salpetrière. Through his kindness I had an opportunity to demonstrate the objective signs in epilepsy in the Charcot clinic, in five cases, and also to investigate ten cases of encephalitis lethargica in a ward of the hospital. The Salpetrière strikes the visitor by the extent of its grounds and buildings. At its entrance is a statue of Charcot. It represents him standing, as if teaching, and makes him an impressive figure, the father of modern neurology. I left Paris with regret, the more so because my itinerary prevented my visiting Dr. Simon, one of the pioneers in investigations relating to measurements of the mentality. Some one has said, "See Paris and die." I would change this to "See Paris and see it again." I hope to.

LONDON

These notes touching upon the school hygiene service in Europe have followed the order in which the representative cities were visited, and fittingly they finish with the city with the largest number of school children, London. In it there are over a half million of children in the eight school grades, averaging 65,000 in each grade. Last year 192,000 were examined in the groups required by law; those entering school life, those between seven and eight years, those at twelve years, and those leaving the schools. Besides these regular examinations, there were 41,348 special ones, of "children found ailing by school nurses, children not attending school brought up by the attendance officers, and children upon whom care committees or head teachers required the doctor's advice." Among these specially examined there were found 112 epileptics, and in passing, I note that this gives a ratio of two and seven tenths epileptics in a thousand school children.

Through the kind attentions of Dr. Ralph Williams, H.M.I., on the School Board, I was enabled to learn the working of the hygiene service in London. He was formerly Director of School Hygiene in Sheffield, and in his work has always manifested a special interest in the problems connected with epilepsy in school children. On my expressing a desire to learn particularly of this phase of school hygiene, he introduced me to Dr. F. C. Shrubsall, neurologist to the public schools. This earnest and genial gentleman did everything to make me happy. He had me supplied with a set of forms used in the school hygiene service and explained their use. There are 125 forms, so that a proper record of everything done in the service is provided for. He gave me a copy of the Report of the School Medical Officer [Sir William Hamer] for the year 1924. From it one can glean the immense amount of good done the children of London, by the school hygiene service. A part of this report that will interest neurologists is that relating to the investigation of encephalitis lethargica cases in London school children, by Dr. Shrubsall. There were 119 cases reported upon in 1924. The prominent symptoms were:

1. Sleep impairment, 40.
2. Paresis or paralysis, 6.
3. Twitchings, tremors or "fits," 12.
4. Occular symptoms, 10.
5. Intelligence impaired, 26.
6. Conduct changes, 44, including: a, irritability and impatience, 17; b, excitability, noisiness, restlessness, 12; c, lack of control, destructiveness, spitefulness, and violence, 8; d, stealing, 2; e, other manifestations, e. g., hysteria, obsessions, suicidal tendencies, 4.

Dr. Shrubsall arranged a visit for me to Dr. J. Tylor Fox, superintendent of the Home and School for Epileptic Children, at Lingfield, about twenty-six miles from London. This is a beautiful and practical institution. Dr. Fox, a master in his specialty, is yet an earnest student. He has a winning personality, that fits him for the office of developing these children. I had the privilege of demonstrating to him the objective signs of epilepsy, the white spots and characteristic skin reactions on several of his little patients. I deeply regret that my stay in London was so limited that I had no time to tap the stores of his experience for my own benefit. However, on my return home, I learned by consulting in-

dices of the *British Medical Journal* that he has published *The Care of Sane Epileptic Children* which you may be sure I have ordered from the publishers, J. Bale, Sons and Danielsson, London.

On my arrival in London I got a letter of introduction to an able practitioner there, Dr. Gilbert Orme. When I told him my desire to meet confreres interested in epilepsy research, he took up the phone and called up Sir Aldren Turner's number, and learned he was away on vacation. I was sorry to leave England without paying my respects to this eminent specialist in epilepsy. Dr. Orme then called up the secretary of the Medical Fellowship Association, Miss Roy, and made an appointment for me with her, explaining to her my wishes. She gave me notes of introduction to the authorities connected with the National Hospital for Epileptics, and the Maida Vale Hospital for the Epileptic and Crippled. At the National Hospital for Epileptics I had the privilege to demonstrate the objective signs of epilepsy to Dr. Collier when he was giving clinical instruction to a large group of medical men, among which was a doctor from the antipodes, another from Chicago. The latter introduced himself to me, Dr. Grinker, son of the doctor who introduced the use of luminal for epilepsy, in the U. S. A. Dr. Collier's clear thinking and logical method of teaching explains the popularity of his clinic. At the Maida Vale Hospital I met Dr. Anthony Feiling and sat two hours in his clinic edified and instructed by his manner of treating patients; his gentleness and firmness with them; his lucidity in presenting rapidly the salient features in their histories. I met no clinician in Europe his equal in these respects. It would be a salutary thing for the future careers of undergraduates to sit in this gentleman's clinic and observe. I cannot but contrast his practical ethics with those of a clinical teacher that I chanced to observe, I wont say where. This latter was being consulted by a beautiful young woman about a change in her occupation. Her malady was epilepsy. He advised her to avoid fatigue, very good advice. He then informed her that she would become worse! Though he believed so, what right had he to frighten her with such an opinion. Had he read Tissot, a practical neurologist of the eighteenth century, he would have learned that fright and terror produce epilepsy; he would have learned how that master cured many cases of the disease, and with the knowledge that recent research gives of the pathogeny of epilepsy, he would have taken an optimistic view of his case and set about curing it. This gentleman had no time to witness a demonstration of the objective signs of the disease. Here again his ethics were at fault, for the teacher true to his calling eagerly seeks new light from whatever quarter upon the subject matter he teaches. He owes this up to dateness to the men he trains.

In bringing these notes of a delightful trip to a close, I desire to heartily thank all the officials I met for their many courtesies. The interest awakened in the school hygiene authorities abroad by my report of the research in epilepsy done at the Forsyth clinic in Boston, will doubtless be reflected in the European services by their planning for the early dagnosis and treatment of epilepsy in school children, the time when its cure is easy. I trust the Boston school hygiene service will not rest with laurels in this respect, but will emulate the magnificent work done abroad, and noted above, in the care of the neglected, chronic case of epilepsy in the school children.

The Need of Psychoanalytical Clinics and Institutes in America*

L. PIERCE CLARK, M.D.
New York

The progress which has been made in the field of neuropsychiatry within the past two decades has been striking, for largely within this period we have seen the formation of mental clinics for the study and treatment of nervous disorders as a necessary part of the curriculum of the medical school. Their existence as a separate entity, however, in different cities and communities has been one of the important accomplishments of the National Committee of Mental Hygiene. While these mental clinics have aimed to render medical and social service and help the individual to make conscious adaptations, their function has not met the great problem of the neurotic wherein the unconscious motivations of his disorder must be brought to light. It seems highly important in order to meet this urgent issue that clinics be devoted to a more careful research of the unconscious forces that precipitate neuroses. There is but one sovereign method of dealing with these nervous disorders, and that is by psychoanalysis, which has been so excellently developed under the leadership of Freud.

It is a question not yet settled whether clinics for the investigation of unconscious activities should become an integral part of the mental clinics or be an independent institute of investigation. Surprising as it may seem, the modus operandi of psychoanalysis is for the most part opposed to direct suggestion as now offered by the mental clinic. To the end that we make another step forward toward investigating and treating the neurotic with limited means by this newer method, I would most seriously urge that psychoanalytical clinics be formed as an integral part of our armamentarium for advancing the permanent welfare of the nervously ill.

I shall undertake to outline briefly what I consider a pressing neuropsychiatric issue at this time, namely, the need of establishing psychoanalytical clinics or institutes in this country for both therapeutic and didactic purposes. If, in the words of Freud, psychoanalysis possesses in addition to its scientific importance a specific means of treatment and is able to aid suffering humanity in the struggle for realization of its cultural requirements, this assistance should be

*Read before New York Neurological Society, October 6, 1925.

extended to the great mass who are unable to compensate sufficiently the analyst for his arduous labors. The economic burden which a neurosis throws upon the individual and his family is only too well known. Unfortunately the need of such clinics is the more urgent for two reasons: first, to overcome the entrenched opposition to this art and science in the curricula of our medical schools, and secondly, to train a larger number of analysts in whose skill one sees the only protection against quackery in this branch of medical science.

My suggestion is not a novel or unique one. Two such clinics have been in existence for several years in Vienna and Berlin. During my visit to the Ninth International Congress of Psychoanalysts which met in Homburg in September (1925). I had a long conference with the heads of both these clinics, and I was particularly interested in the development of the one in Berlin. In 1918, Freud stated that the time was not far distant when it would be regarded as the urgent duty of the state to give aid to the soul as to any other lifesaving and health promoting agent, and thus psychoanalysis would be made accessible to an increasingly wide circle of peoples in all conditions of life.

The difficulties encountered by Dr. Eitingon and his colleagues to establish the Polyclinic in Berlin are somewhat similar to those experienced in this country. After the World War they found that neurotic disorders had grown without measure and the confidence of the public in psychoanalytical procedure had kept pace with this urgency for relief. Not only had the war demonstrated that the Freudian mechanisms in their most flagrant manifestations were patent to the initiated, but they were almost equally obvious to the unskilled and prejudiced. Under the stress and misery of the war it seemed that a sort of Utopian policy was about to be put into operation, for the government officials apparently were willing to do almost anything to advance the cause of the nervously sick. When the collapse came, however, they not only withdrew their sympathetic support but actually became hostile to all former promises. In this country, immediately after the Armistice, we all know how even the more popular and well established institutions suffered. In many instances their very existence was threatened. In the rapid overturn of politics and policies even a fair degree of progress in scientific research was extremely difficult. It is, perhaps, but a natural heritage of war to expect this attitude to follow in economically depleted countries, but certainly we were not exempt from this calamity, and private means for promoting research, which has always been our strongest point, had to be requisitioned. Under similar arrangements in Berlin psychotherapy continued to advance.

Abroad as well as here the lay and medical public ask the question: How can psychoanalysis ever hope to solve more than a small part of the psychoneurotic problem, with a system of individual treatment and prolonged analysis of the single case? This need not trouble us so greatly if we but follow the wise course of the Berlin psychoanalysts, who did not shrink from even small beginnings and were willing to devote the necessary time to the task. In 1919 the operation of the Berlin Polyclinic began in a moderate way with three assistants and was privately financed over a term of years. Several volunteer assistants were added, but the burden of the work was carried forward by the full time staff. Later the staff increased to seven members who devoted jointly twenty-seven hours daily. This did not include the private analyses of the psychoanalytic union which consisted of a supporting outside group of psychoanalysts as well as analyses made under the clinic's control by the students of the Polyclinic.

In three years the polyclinic found itself pressed for space beyond the five rooms at its disposal. Furthermore the loose or democratic union had to give way to a more consolidated working system under the fixed control of its two founders, Dr. Eitingon and Dr. Simmel. Members of the staff received a fixed remuneration which bore no relationship to the amount of time given or the work actually accomplished.

Directly after opening, twenty analyses were undertaken, and at the outset, as is characteristic in all new mental clinics, many inveterate neurotics for the most part unfavorable for analysis, presented themselves. Soon, however, this class gave way to the more suitable cases, such as conversion hysteria, anxiety states and compulsive neuroses. The intelligent and professional class as well as the lower middle class of working people of all ages came to the clinic. Physicians as well as patients continually recommended the clinic. Patients were seen daily with the exception of one day a week kept for didactic purposes. An attempt to reduce the time of each session to half an hour was abandoned, for there was only a small number of army officials, etc., accustomed to discipline, who were able to cover sufficient ground in the shorter period of analysis. Usually three quarters or the classic full hour was required. The patients came on an average of three or four times a week and were seen oftener in severe cases. One hundred and thirty analyses were carried out, which is indeed an imposing number for such careful and searching analyses as were given, and in 1922 the clinic was able to make a formal report of statistics (1). The question of hastening or shortening the treatment was given constant consideration, but such a plan has met with little success despite zealous employment of the requisite time. The delay in the waitingroom had a favorable influence on patients, for the neurotic realizes that many others are in the same predicament as himself. The lack of interest in the personal material on the part of the analyst strengthens the first position notably and makes much resistance at once threadbare. One circumstance of polyclinic treatment has given many colleagues both within and without the clinic much perturbation, and that is the question of an honorarium. There is the fear that the clinic is endowed with both the means and the opportunity to bring out certain complexes like the analerotic; they have marveled that these fearful patients seem to have missed seeing a very interesting sentence in the Budapest paper by Freud. The latter, who quickly recognizes the slightest malice in the soul of the subject and the most shadowy aggravations of the technic, states in speaking of the institutional psychoanalytical treatment of the future with the sovereign assurance peculiar to him: "This treatment will be without charge." Now the polyclinic has not this principle of "no pay." From prac-

tical and educational reasons the staff desires and expects that the analyzant shall pay, as much or as little as he is able. One man may pay nothing and another may pay well, and it cannot be said that this matter of payment has any influence one way or another on the success of the treatment. If as representative of the institute and again individually the patients who stand in the neurotic constellation are permitted to pay little or nothing, the clinic's analyst plays for a time the "father rôle" and in many cases the "mother rôle"—the rôles, therefore, which the patient forces upon the analyst. This rôle is played until the proper time when the analyst can take this point up with the patient. Up to that moment the analyst rescues or makes possible quite a few analyses which would have been impossible in private practice, and at the same time he broadens the field of those who come for analysis. The clinic does not, of course, come to wholesale therapy, which would be impossible in a polyclinic. We must remember that we are speaking of making analysis more accessible and while Dr. Eitingon believes that all of his staff are highly and justly satisfied with the work of the Polyclinic, he does not look upon the latter as having reached its limits of success although the present results are highly gratifying.

All who have had experience with "fractional analysis" whereby through external circumstances interruptions of the treatment become necessary, find it does no harm provided the analyzant has reached a certain stage of improvement. Since the aims of the clinic are more practical and therapeutic than scientific, in certain cases one may make capital out of this fact and erect a sort of principle. If the patient's condition has improved; if he has through the clearing up of his internal condition gained a large degree of functioning, the analyst can often interrupt his treatment and demand that he profit by what he has already gained. He may and should come back if his gain is not satisfactory. This resumption of treatment often shows that an acceleration of the tempo of improvement is present and he may continue to improve until cured. As Freud states, the most important constituents of analytic treatment will surely remain those which are borrowed from *strict* and *aimless* psychoanalysis.

As the number of patients increased the Polyclinic required an almost continuous increase in the numbers of its staff, and the question arose in regard to training assistants. There was a demand for teaching analysis in order to educate analysts. This was the second aim with which the staff entered upon the foundation of the institute. Introductory lectures and orienting addresses have, of course, already been instituted in most local groups in order to diffuse knowledge of psychoanalysis. The staff at once proceeded to hold regular and systematic instruction and education by courses. With Dr. Abraham at the head, Dr. Eitingon with his colleagues Dr. Simmel and Dr. Sachs, supported by the staff fellows Dr. Horney and Dr. Liebermann, there was formed a small teaching body for carrying out an educational program which embraced the following subjects: An introductory course in psychoanalysis; a psychoanalytical seminary for the advanced student; an introductory course on "experiences from psychoanalytical practice." During the course Dr. Sachs brought up the question of the application of psychoanalysis to the mental sciences; the theory of dream interpretation; the technic of dream interpretation, sexual problems of psychoanalytical practice; and held seminaristic exercises on the application of psychoanalysis. Dr. Horney and Dr. Simmel spoke on the psychoanalytical viewpoints for the medical practitioner and Dr. Simmel also on psychoanalytical technic. Dr. Eitingon held alone or jointly with Dr. Simmel three or four times a year a practical course without time limits on the introduction to psychoanalytical therapy. Here the pupils who were to learn analysis must have already completed self-analyses, but in the case of practitioners of medicine this was omitted, for their only desire was some orientation in a subject which they did not intend to practise.

It is a firm and all too well founded conviction that no person who has not been analyzed should become a member of the ranks of practising psychoanalysts. Passive selfanalysis takes a decisive place in the education of the analyst and is given in the latter part of the course after intensive theoretic preparation by lectures and courses. In regard to selfanalysis it was made further possible by the activity of Dr. Sachs who was called to the polyclinic to conduct didactic analyses among the patients.

The number of pupils analyzed wholly or partly as part of their training during the two years 1920-1922 was twenty-five, comprising thirteen men physicians, five women physicians, one medical student, five teachers or others who wished to make professional use of analysis and one woman student of ethnology. Of the twenty-five, nine were from outside of Germany, as follows: one Austrian, four Hungarians, one Hollander, one American, two Englishmen. Of the twenty-five only eight had previously studied analysis and four of these were members of the local Berlin group while ten were standing guests of the same. Thirteen were analysts, one for children only. Two who were analyzed became members of the staff after completion of their course. A particularly important part of the managed course of instruction was the work of the polyclinic, which was something new in psychoanalysis. It was not easy to find the best way to conduct this work, although apparently there was but one way available. Whatever seemed venturesome was modified by increasing control. Through theoretical studies and selfanalysis already well prepared consultations with patients was entrusted to pupils, when suitable for beginners. The pupils were allowed to take the first steps of analysis alone, and required to keep an accurate record, and with this as a guide the teachers were readily able to make corrections. In this way the host of errors made by the beginner, due to defective comprehension of the aims and methods of analysis and too rigid adherence to single findings was avoided.

The Polyclinic feels satisfied with the results of its teaching activities, for the pupils have learned much and well and have shown the soundness of the idea. But this is only a beginning even if the outlook is of the best. The possibilities of the project are yet to shape themselves and they hope to make strides in the right direction in the not too remote future.

From the foregoing account of the establishment

and working of the Berlin Psychoanalytic Polyclinic we are made aware that though the organizing of such clinics or institutes differs from other medical clinics, such institutes in this country are not only feasible and practicable but are a matter of the utmost urgency. I do not believe they should be organized on the lines of the ordinary mental clinic or be an integral part of them at the outset; later when the didactic functions of such clinics come to the fore the need of their close affiliation with neuropsychiatry and psychiatry will be obvious. The great fault today is that the average trained psychiatrist knows too little of the discipline of psychoanalysis and *vice versa*. Psychoanalysis in theory and practice must be an integral part of any thoroughgoing system of mental science. This is the purport of the wise address of Dr. White in this year's presidential address before the American Psychoanalytic Association, and I believe this is the conclusion to which most well trained psychiatrists in this country today would subscribe. Will it be possible for us to overcome the curricular prejudices of our medical schools so that this important method in neuropsychiatry may be an integral part of the training in our schools, or shall this prejudice force an independent existence of such clinics or institutes outside the regular training of physicians in neuropsychiatry? Already active attempts to organize private and semipublic pay clinics are being made in this country. Can neuropsychiatry afford longer to ignore this public demand?

In conclusion I submit:

1. That psychoanalytical clinics and institutes are a necessary part of our armamentarium for the therapeutic alleviation of the large mass of neurotics who cannot afford to pay for psychoanalysis as now practised.

2. That such clinics are necessary for maintaining a consistent school in the training of psychiatrists and psychoanalysts, and thus obviate the present tendency to quackery in this specialty, the detailment of which is the active agitation of the daily press and which is largely due to our neuropsychiatric neglect.

3. That these clinics should be independent in organization but allied to our medical schools and hospitals.

4. That full time service of the resident staff should be expected with a controlling or advisory board of analysts to support and give direction to the therapeutic and didactic work of the clinic or institute.

The Fallibility of the Intradermal Tests with the Grasses in Chronic Perennial Bronchial Asthma: Hypodermic Tests*

I. S. KAHN, M.D., and
EMMA M. GROTHAUS, Technician
San Antonio, Texas

The pollen materials used in this report were the ordinary 1:50 commercial testing extracts of Bermuda and Johnson grasses (Capriola dactylon and Andropogon halepensis) of the Arlington Chemical Co., and special Berkefeld filtered 1:20 extracts of timothy, Sudan, Johnson, orchard and blue grasses, prepared by extracting for four days, five gm. in 100 c.c. of Coca's solution thirty-three and one third per cent. and glycerin sixty-six and two thirds, after acetone treatment. All tests were done intradermally with a dose of 0.01 c.c. The potency of each lot of the material used was satisfactorily determined on known sensitive controls; the tests were performed not once but repeatedly, often with each of the extracts mentioned in 1:50 dilution, and usually with more than one lot of the extracts, eliminating thus the questions of poor material and errors in technic. Positive tests when secured were graded as follows:

A wheal 0.5 cm. to 0.75 cm. .....+
0.75 cm. to 1 cm. .....++
1 cm. to 2 cm. .....+++, with pseudopodia ++++.

In this connection, it might be stated that an intradermal injection of 0.01 c.c. of a glycerinated extract of 1:50 strength of any pollen may produce a wheal one cm. in diameter with a slight surrounding erythema, but without pseudopodia, in any individual, allergic or otherwise. Local cutaneous reactions, indurations, erythemas, secured during treatment, or as a result of hypodermic tests, were graded according to the same scale. Cases tested were kept under observation at least an hour and seen again the next day.

Texas is composed in the main of farming and ranching, and not industrial or manufacturing communities, with few large cities and few forests. Most of the state, especially the southwestern section, possesses a mild climate with considerable areas of limited rainfall and high winds, conditions conducive to abundant air borne pollen production with wide dissemination. Hence, the vast majority of our hay fever and asthma cases are of pollen etiology, and in our section of the state, usually of the chronic perennial type. Owing to the lack of rain and comparatively high wind velocity in the fall and early winter months, our pollen air content reaches its maximum at that time, with consequent coincident maximum clinical suffering. We rarely see grass hay fever or asthma limited to the spring months as elsewhere. Such cases with us are practically invariably either fall or early winter cases as

*Read before the American Society for the Study of Allergy, Atlantic City, N. J., May, 1925.

well, or perennial in type, with a period of heightened autumnal intensity.

Our first heavy frost usually comes about January 10th, but the ragweeds and carelessweeds die out in late November, an appreciable number of weeks previously, and coincidently, our untreated ragweed and carelessweed cases clear also in November, with the disappearance from the air of these two factors. Therefore, the history of the duration of symptoms of hay fever and asthma is as important with us as elsewhere. Also we do possess, in the grasses, a highly antigenic possible pollen etiological factor for our cases of perennial hay fever and asthma that might not exist elsewhere, in addition to a succession of other typical seasonal pollens (1). Actual air pollen analyses have shown that with us a heavy frost reduces, but does not remove completely, grass pollen from the atmosphere as might be expected.

On the Texas gulf coast, where many of our population spend their summers, from June to September the winds for approximately twenty-eight days out of thirty blow off the water, and pollen cases residing anywhere near a beach pass those months either totally or almost totally clear. As heavy frosts and freezes are practically unknown in that section, the grasses pollinate unceasingly the year round. The winds are decidedly frequently from the land, except in summer, and such grass pollen cases in fall, winter and early spring, do not secure anything approaching the satisfactory relief attained during the hot months. On the other hand, mountain cedar, our only other winter pollen, does not grow within one hundred miles of the Texas gulf coast.

This condition gives us a splendid opportunity to remove in a practical manner our pollen cases from pollen contact for a consecutive number of weeks during pollination season. Consequently, direct observation, or a history of the fact volunteered by the patient, of complete disappearance of allergic symptoms of the respiratory tract on the coast in summer, is of decided significance, especially if confirmed by a story of annoyance following inland trips, or a recurrence of trouble beginning in September, when the land breezes become more frequent. It might be added that the ragweeds also die out there in late November, as with us.

It goes without saying in this discussion that experimental contacts, as well as skin tests, have ruled out the influence of other antigenic factors, such as feathers, animal hair, foods, orris, etc. Cases are being considered only in whom symptoms continue notwithstanding the breaking of such other contacts.

It might also be added that with us the ragweeds as uncomplicated causes of hay fever and asthma are rather rare. Of 185 pollen or presumably pollen cases seen in the last fifteen months, out of a total number of 212 cases of hay fever and asthma, sixty-five per cent. of whom were asthmatics chiefly of the chronic perennial variety, we had only five cases of pure ragweed hay fever and one of asthma. In the same way, we see few cases of pure fall hay fever and asthma; in practically all of such cases the patients suffer also in winter and spring, especially in May when grass pollination is extremely high and when the air contains no Compositæ or Amaranth pollen granules. On the other hand, the grasses were proved factors in eighty-nine of our one hundred and nineteen known proven pollen cases as shown by history, skin tests and direct exposure to atmospheric pollen.

Consequently, from the statements and figures mentioned, the allergy worker in San Antonio and Southwest Texas must consider the possibility of pollen, and especially grass pollen, as a causal factor in every asthma case, seasonal or nonseasonal. So naturally our attention has been turned toward the etiological bearing of this particular antigen in all our perennial cases in which the ordinary grass pollen intradermal tests are persistently negative or only slightly positive, which study as a corollary, of course, determines the actual practical value of this usual method of testing for the detection of grass hypersensitiveness in chronic perennial asthma cases.

The skin response to pollen extracts in hay fever and asthma of such etiology is usually very prompt. Large typical wheals with pseudopodia are the rule, and are obtained not only with the ordinary 1:50 strength testing extracts, but with dilutions of 1:500 and frequently of 1:5,000. This description fits the ordinarily reported ++++ reaction. It is the custom of almost all workers in the field of allergy to accept as etiological positives only such reactions as are evinced by a wheal accompanied by definite pseudopod formation.

For several years, we accepted this usual criterion, but the failure to secure results in certain cases with either totally negative or mildly positive pollen tests, also negative or positive to other allergens, and assumed therefore of nonpollen etiology in spite of suggestive pollen histories, led to the assumption of the possible fallibility of the pollen skin tests in certain instances, and the endeavor to secure a method by which such error could be avoided. Naturally, our work has been limited altogether to our most predominant pollen—grass. In this connection, we have been unable to distinguish any reactive or curative differences between any of the grass extracts we have used—timothy, Sudan, Bermuda, Johnson, blue or orchard grass. Patients sensitive to one are apparently sensitive to all, as far as we can make out by tests and histories, and practically equally so. Desensitization by any of these six mentioned gives protection, at least locally.

The ophthalmic test, owing to its lesser sensitiveness, as reported by Vander Veer (2), we have not used. Also, in these severe chronic asthmas, our usual type, we have dreaded to spray dried pollen into the nose or trachea.

The assumption of the possibility of the existence of hay fever and asthma due to the grasses in the absence of any initial positive grass tests was reached from the following clinical observation.

It has been our custom to retest our cases constantly during the desensitization process, endeavoring in every instance to reach a desensitizing dose of sufficient strength to obliterate the initial positive diagnostic skin tests. Once this point was attained, it should apparently indicate the elimination of hypersensitiveness to that particular pollen, given, of course, the employment of undoubted potent testing material. In our experience with grass cases and extractions, reduction from a ++++ to a bare + is practically always possible with rare exceptions,

and decidedly frequently a complete obliteration of the initial commercial 1:50 testing extract positive is secured when treatment has been pushed to the use of 0.1 c.c. to 0.2 c.c. of a 1:20 extract. However, in many instances, obliteration of the positive skin tests with the inception of the use of the 1:20 dilution does not correct the allergic respiratory symptoms in coseasonally treated cases, and has not prevented the appearance of hay fever or asthma in preseasonally treated cases as we learned to our chagrin. This would make it appear that a diagnostic error had been made, were the commercial diagnostic tests, that is those in use by the average worker, infallible as a test of clinical hypersensitiveness to these grass pollens. Otherwise, clinical symptoms should cease with the demonstration of the obliteration of the positive skin tests, and symptoms should not later appear in preseasonally treated cases when this point has been attained as a result of treatment, or else some other factor is involved in the case. By clinical study, a protective grass dose in our vicinity varies up to 0.5 c.c. of a 1:20 dilution, and is seldom the 0.3 c.c. of a 1:100 dilution as commercially advertised as sufficient. When these larger doses mentioned have been attained by us, these same grass hay fever and asthma cases do clear up, and preseasonal cases with such doses are almost invariably protected, which fact practically eliminates the consideration of extraneous factors. Hence with us, the securing of a later negative skin test with the ordinary commercial extract definitely positive at the beginning of treatment, does not mean complete or even nearly complete clinical desensitization.

It is a well known fact that the degree of sensitiveness to allergic factors varies in various individuals. This is, of course, demonstrated easily by the response to various serial dilutions at the onset of desensitization treatment. In some cases the patients easily tolerate at once doses of a 1:1,000 dilution; with others, treatment must be started with as low as a 1:50,000 or even a 1:100,000 extract. Nor is severity of symptoms any indication of the degree of sensitiveness actually present. Heavy doses in a mildly sensitive person will produce as severe symptoms as light to moderate doses in a person of a lesser degree of sensitiveness. With us, the condition of heavy atmospheric pollen doses is continued over many months, not weeks, giving abundant opportunity for producing severe protracted symptoms in patients actually, comparatively speaking, possessing no great degree of hypersensitiveness.

The following question also must be taken into consideration: Does the intradermal test invariably indicate the degree of sensitiveness present? Is such sensitiveness limited to the nasal or bronchial mucosa with at times the skin not implicated?

In support of this idea of the absence of any such parallelism, is the fact that, while involvement of the skin, bronchial, nasal and ocular mucosa, and even at times the circulatory system, in the severe constitutional reactions of anaphylactic shock following overdoses from pollen extracts certainly at times occurs, such widespread general involvement is not invariable, vasomotor rhinitis and asthma occurring under such circumstances much more frequently without, than accompanied by, angioneurotic edema or urticaria. Also it is at times possible to have constitutional reactions suspiciously or even undoubtedly due to treatment, without the slightest evidence of erythema, induration or wheal formation at the site of the needle injection puncture. As additional confirmation of this point, it has long been recognized that positive skin tests are notoriously difficult to elicit in the aged, no matter how severe the asthma. If grass hay fever and asthma can continue unmodified even after the desensitization has been carried to the point of the elimination of the initial positive diagnostic skin tests, later to clear up even during pollination season by the employment of stronger extracts in higher doses, obviously then, the nonappearance of the expected intradermal grass test cannot be safely regarded as an indication of the absence of grass hypersensitiveness. This might suggest one possibility—that the hypersensitiveness in these cases could be detected by the employment of an extract of a strength greater than that of the ordinary commercial grass extract. Much to our surprise, we found this seldom to be the case. When 1:20 or 1:10 extracts are employed after the elimination of the commercial 1:50 extract positives, the positives secured are only decidedly questionable, frequently only a+ or ++, never the expected ++++ that would be of clinical unquestioned value. (This does not, of course, preclude the possibilities of securing positives with a testing extract of greater strength if we knew how to prepare one.) That this does not represent merely a local exhaustion of the reactive powers of the skin from treatment, is shown by the fact that these cases continue at such times to show unmodified, their original positive reactions to feathers, animal hair and other antigens.

Whether in these old grass asthmatics with lapse of time, the upper layers of the skin gradually lose an original reaction power, is purely a matter of surmise. Whether there exists some factor peculiar to grass pollen extracts which makes them, under some circumstances at present unknown, less antigenic to the skin, while still highly antigenic to the nasal or bronchial mucosa, is also purely a matter of speculation. If pollen asthma represents a further stage of pollen hay fever due to lessened resistance, and the skin reaction represents this degree of resistance somewhat as does the von Pirquet test in tuberculosis, then our figures are rather significant. While of our thirty-five known grass pollen hay fever cases, as shown by history and direct observation of pollen contact and withdrawal, only five or fourteen per cent. gave a ++ or less diagnostic test, and the other eighty-six per cent. the usual ++++ response, or response large enough to be undoubted, in a similar group of 112 grass asthma cases, the obvious ++++ positive reaction was seen in only fifty-nine or fifty-two per cent., about two thirds the percentage of what was found in the hay fever cases. In other words, just under one half of our chronic grass asthma cases gave a ++ or less skin reaction to the ordinary intradermal test, merely wheals 0.5 cm. to 1 cm. in diameter without pseudopodia, and without the irregularity of outline distinctive of the specific positive reaction, tests ordinarily considered negative. Cases entirely negative to all the skin tests are taken up later. A method of testing which misses

a proportion in the neighborhood of fifty per cent. can scarcely be considered infallible or even reliable. In contradistinction to these findings, are our almost invariable ++++ reactions to the other pollens of this community—ragweed, carelessweed and mountain cedar. Curiously enough, we see practically only hay fever, and almost never asthma due to these other pollens. Also where sensitiveness to grass exists coincidently with sensitiveness to other pollens, the skin response to the grasses even when positive, is almost never as large as the corresponding positives to such other pollen or pollens.

Another curious fact is, that while in our work intense urticaria and erythema multiforme have frequently accompanied the constitutional symptoms due to overdosing with ragweed and carelessweed pollen extracts, we seldom or never see any or but extremely slight skin involvement with the most intense asthma resulting from overdosage with grass extracts.

Obviously, then, in these grass cases, minor degrees of positive reactions, a + or ++, may be of decided clinical significance. Whether this would hold true elsewhere where grass pollen is less abundant and of short seasonal duration, is of course only problematical.

The following case illustrates this point:

Case I.—Mrs. C. H. F., aged twenty-eight, was seen September 9, 1924, with very severe perennial hay fever of four years' duration. Intradermal tests: ragweeds ++++; Bermuda and Johnson grasses +. On account of the case being first seen during ragweed season, it was decided to postpone ragweed treatment and try the experiment of desensitizing against the grasses. Treatment was started with a 1:5,000 extract on September 16th, and given at least once a day when absence of reactions permitted. Local reactions were rather numerous. Improvement started at once. Treatment was completed on January 5, 1925, the final dose being 0.15 c.c. of a 1:20 extract. In this case the patient lost her hay fever completely under grass treatment by the middle of October, the extreme height of the ragweed season. Obviously the + grass tests were actually more significant than the ++++ ragweed. (This case gave a ++++ reaction to a 1:500 dilution of ragweed.)

If now, a rather appreciable percentage of known proven grass asthma and hay fever cases give merely insignificant questionable positive diagnostic skin reactions, it is perfectly natural to go a step further and assume the possibility of the existence of similar grass pollen etiology in cases with absolutely negative intradermal tests to all antigens, or as an actual complicating antigen, in cases with negative grass tests and definite positive reactions to feathers, hairs or other allergens, presumably making these latter the sole etiological antigenic factors.

During the past fifteen months we have had nine cases of hay fever and asthma giving repeatedly negative skin tests to all allergens. We have also had the opportunity to keep under observation seventeen other cases of asthma whose pollen tests were negative and who hence were ascribed originally entirely to other allergens that were positive, in whom the persistence or recurrence of the asthma in spite of breaking of such contact, led to further study. All of these cases were reinvestigated from the point of view of grass pollen etiology. A revision of the history of a number of these cases showed stories such as being better indoors, out of a draft, freedom during summer on the sea coast or on an ocean trip, relapses during or following automobile rides or in high winds, increase of symptoms during the height of pollination season, and freedom from symptoms during residence in a downtown hotel in a large city (out of pollen contact).

At times highly probable proof is afforded in these cases as for instance:

Case II.—One of us (E. M. G.) had been a chronic perennial asthmatic of many years' duration, and practically an invalid for years on heavy doses of adrenalin several times a day, asthma originating in Ohio. A severe complicating sinusitis had required several intranasal operations, all unavailing as far as the asthma was concerned. There was no definite hay fever. All skin tests were repeatedly negative except to feathers and wool, easily eradicable factors in our community. Four years ago, after not being clear a day for two years, in desperation, as an experiment, work downtown was ordered with immediate cessation of the asthma as a result, which cessation has been practically permanent in spite of persisting severe, purulent sinusitis. A few months ago, while working in the office, a bottle of 1:20 grass extract broke in her hands. Hay fever and slight asthma immediately followed, and have repeatedly followed the handling of this extract. Desensitization to grass has been found exceedingly difficult on account of numerous local and constitutional reactions during the process. Even after the discovery of this pollen extract hypersensitiveness, with much experimenting, it has been impossible to secure the slightest positive intradermal tests with any of the grass extracts at our command.

If this contention is correct, that grass pollen is the actual etiological factor in at least some of these apparently nonallergic cases of hay fever and asthma, then a certain number of patients should secure relief from symptoms by grass pollen desensitization done in the usual manner. This was done in sixteen cases. As a result, for the first time in years, complete or very marked relief lasting many months so far, was secured in twelve or seventy-five per cent., all severe perennial cases. Of the other four, two are better, the other two showing no improvement. Two other cases could not be desensitized on account of repeated severe constitutional reactions to minimal doses of grass extract, but clear up completely for weeks on a stretch as long as an indoor existence is maintained.

It is going too far, of course, to assert that all nonskinreacting cases of hay fever or asthma are grass cases. There probably exist other allergens where the skin at times fails to respond. House dust can be eliminated in these cases as most of them maintained their indoor existence in their own homes under identical house environment.

The following cases are typical:

Case III.—M. E., aged seven, first seen September 16, 1924, had her initial attack of asthma in El Paso, Texas, at the age of one year, starting in the spring and lasting four months. She lived in Shreveport, La., for several years, and was entirely clear. After moving to San Antonio, she was clear for a year.

Her trouble returned in June, 1923, and had persisted rather steadily ever since, except when on the gulf coast in summer where she was invariably totally clear. Had always slept outdoors. Intradermal tests to pollen, animal hair, orris, glue, horse serum, tobacco and sixty foods were all negative. Owing to the history, pollen etiology was suspected, and the patient was kept indoors under pollen precautions with immediate relief. Attacks could be brought back at any time by playing in the grass. Hypodermic tests:

		Reaction
September	20, 0.05 c.c., 1:5,000 extract of Sudan grass	0
	22, 0.05 c.c., 1:500 " " " "	0
	24, 0.05 c.c., 1:50 " " " "	0
	26, 0.1 c.c., 1:50 " " " "	0
	28, 0.2 c.c., 1:50 " " " "	0
October	5, 0.05 c.c., 1:20 " " " "	0
	7, 0.1 c.c., 1:20 " " " "	0
	9, 0.15 c.c., 1:20 " " " "	+++

In addition to the local skin reaction, a rather sharp attack of asthma developed within an hour after the last dose. Desensitization was then started, beginning with 0.1 c.c. of a 1:20 extract. Reactions of + to ++ were repeatedly secured during desensitization, and more than once were accompanied by asthma. The final dose used was 0.25 c.c., repeated several times. The asthma cleared up completely within three weeks and has not returned.

COMMENT.

This case represents the type of a low degree of sensitization. The El Paso grass problem is almost identical with that of San Antonio—winds and dryness producing abundant high pollen atmospheric content, sufficient to give symptoms in a case possessing no great degree of hypersensitiveness, not enough to have symptoms in Louisiana where rainfall makes atmospheric pollen less abundant.

Case IV.—J. M. S., schoolboy, aged fourteen, was first seen on May 1, 1924, with steady asthma of two weeks' duration. He had a history of attacks two or three times a week for ten years past. Had always lived in San Antonio. Attacks were always worse in winter, clearing every summer (which was invariably spent on the South Texas gulf coast). Attacks were worse at night. Said he had had a "cold" for about nine months with much sneezing. Sleeps on cotton pillows on the coast, but on feathers at home. No animal pets or chickens. Skin tests: chicken feathers ++++, horse hair +, wool ++, human hair +++, cattle hair ++++, camel hair +++, goat hair ++, rabbit hair ++, cottonseed meal ++++, nuts ++++ and various other foods +++ and ++++. Pollens: ragweed +, grass +. The history and the tests were decidedly suggestive of a feather-hair-food case. An outdoor life was ordered, feather pillows removed and suspected foods, suggested by the tests, eliminated. No improvement occurred. During May and June, wool desensitization was started with no improvement. From June 19th to September 15th this patient was on the Texas gulf coast as usual, and entirely clear, taking no dietary precautions. On returning to San Antonio, asthma started again at once, being almost daily. All pollen tests were again negative. Routine pollen precautions were instituted with immediate improvement. Hypodermic tests gave a ++++ reaction with 0.2 c.c. and 0.25 c.c. of 1:20 grass extract. Grass desensitization treatment was started on September 29th, beginning with 0.05 c.c. of 1:50 extract. As this was a coseasonal immunization, started at the height of the pollen season, numerous reactions, local and general, occurred. The final dose of grass extract used was 0.4 c.c. of 1:20 dilution of timothy. The last asthma occurred about Christmas, 1924, and the boy has been entirely clear ever since, for the first winter in his parents' recollection, though he eats what he wants and has been back on feather pillows for months.

The strong feather and hair tests, confirmed by a history of winter asthma, with negative pollen tests, caused the natural error of overlooking the actual significant allergic factor in this case—the grasses.

As further corroboration, these cases are not particularly easy to desensitize, local and constitutional reactions occurring during treatment just as frequently as with the cases giving good initial positive skin tests. Obviously, the deeper cutaneous tissues do not share in the lack of sensitiveness evinced by the upper dermal layers involved in the intradermal tests. We have not had a single relieved case who has not shown local and constitutional reactions during grass desensitization treatment, and we have had several whom we have not succeeded in immunizing at all after months of effort due to repeated constitutional reactions with minimum doses. One of these, with repeated negative intradermal grass tests, under treatment for months, cannot pass 0.05 c.c. of 1:5,000 of any grass extract without a local reaction and asthma lasting days. This same case will remain clear at any time indoors.

The occurrence of such local reactions during desensitization treatment naturally suggested the idea that advantage might be taken of such reactions intentionally produced for diagnostic purposes, and for the past year such is our routine where the ordinary intradermal grass pollen tests are negative or unsatisfactory.

HYPODERMIC TESTS.

Technic.—The injections are given daily or every other day in the biceps region, the dose being raised until definite indurations 1.5 cm. to 2 cm. in diameter are secured, usually accompanied by erythema. Further dose increase will be accompanied by constitutional symptoms, the severity of which will vary according to the rate of dose increase, but which with proper care need be only slight. Such constitutional reactions, of course, increase the diagnostic value of this procedure. It goes without saying that the risks involved and the objects of the test should previously be explained to the patient. The following doses are recommended:

1:5,000 dilution:	0.05 c.c., 0.1 c.c., 0.25 c.c.
1:500 "	" " "
1:50 "	" " "
1:20 "	0.05 c.c., 0.1 c.c.

The desired positive reactions are almost invariably secured by the time the 1:50 dilution is reached, ordinarily in either the 1:5,000 or 1:500 dilutions. Following their subsidence, either with or without the use of epinephrine, desensitization can be proceeded with in the usual manner.

The following case illustrates the value of this procedure:

Case V.—M. C., schoolgirl, aged fourteen, seen December 29, 1924, she had had asthma off and on for ten years, nonseasonal in type. She had always lived in or near San Antonio. Knew she could not stand much face powder. The only time she had been free from asthma was for six months when the family kept no chickens. Her father could not use feather pillows. The present attack of three days' duration followed picking chickens. Intradermal tests: feathers (including those from her own chickens and pillows) 0 or +; foods, 0; orris root, +; pollens, 0; chicken feed, ++. This patient naturally suggested feather or chicken feed etiology. However, the case was cleared under epinephrine and an indoor, closedup existence. On December 31st, she was given a hypodermic grass test of 0.1 c.c. of 1:5,000 dilution of Johnson grass with a negative reaction. On January 3, 1925, she was given 0.1 c.c. of 1:500 dilution of the same grass with ++++ local reaction consisting of induration and erythema. In confirmation she was told to take a long auto trip into the country on a windy day and to walk in grass and weeds. This was done four days later, resulting immediately in hay fever and asthma. There was no possibility of feather or chicken feed contact.

Indoor existence keeps this case clear in spite of feather pillows, but she will have asthma if she spends very much time outdoors in windy weather. The grass hypodermic tests, confirmed by environmental grass pollen contact prevented us from falling into error on account of the negative intradermal grass tests in this instance, and calling this a feather or chicken feed case. Grass and mountain cedar pollen were the only pollens in the air at the time. The history eliminates mountain cedar; moreover, we have never seen a negative skin test mountain cedar case.

In past years we have had a number of instances of asthma and hay fever with definite feather, animal hair or food positive skin tests in whom the pollen tests done coincidently were absolutely negative. We have, as a result on such occasions, advised our patients that the elimination of such factors from their environment would bring about a cessation of their symptoms. At times this has, of course, been the case, but in various other instances we have been mortified and baffled by the unchanged persistence or return of the asthma following the proven removal of these antigens, having placed full dependence on the negative pollen tests, never dreaming of a possible pollen etiology. Undoubtedly, our experience in that particular has not been unique.

With the recognition of the noninfallibility of the pollen tests, at least as far as the grasses are concerned, and the routine performance of the hypodermic tests corroborated by clinical improvement following the institution of indoor existence and pollen precautions, we have found a means of avoiding such an embarrassing situation. It must be admitted that these grass hypodermic tests have never been done except on such patients whose history or environment suggested the possibility of grass etiology, or in whom an indoor existence, away from pollen, gave some measure of relief, and we have never had a single case that did not respond to one of the grass dilutions employed. Proof of the scientific value of this procedure would certainly be much more conclusive were we able to report negative reactions to high strength extracts in normal controls or in proven animal hair cases. This experiment we have been tempted to try on several occasions, but have never done so for fear of inducing thereby a sensitiveness hitherto nonexistent.

The value of this procedure is shown by the fact that it has enabled us to diagnose and relieve completely, either by desensitization or pollen precautions, a number of cases apparently nonallergic, and also a number with definite positive skin tests to other allergens, where the positive tests secured had apparently little or no bearing on the actual etiology of the asthma or hay fever, as shown by the continuance of the symptoms.

We are not prepared to state that this is a specific reaction or that the results are due to the specific desensitization secured, as in our hands a high immunization against the grasses frequently gives a high or even complete protection against ragweed and carelessweed, completely obliterating the +++ or ++++ positives secured with their extracts at the inception of grass pollen treatment, as reported previously (3). Still, on the other hand, we know of no work on air pollen analysis in the north that would tell definitely the disappearance or appearance of grass pollen in the air. We have actually found such grass pollen in the air of both Kansas City and Chicago in late August or early September, but have had no further experience.

There is also the possibility that the increase in symptoms in these cases in the winter months is due to the nonspecific action of winds and cold air on an originally specific grass basis. Many of our cases of this type are worse in winter, at a time when grass pollen exists in the air to a far lesser degree than in warm weather, and an indoor existence naturally also eliminates this factor and may account for some of the improvement secured.

We have also had recently three cases of grass-ragweed asthma (positive skin tests) starting in Chicago and St. Louis in winter, and one from Cincinnati starting in February with negative intradermal tests, positive by hypodermic tests, where elimination of feathers, wool and suspicious foods gave no relief, until pollen precautions were started, the inception of whose asthma was far out of the usually recognized grass or ragweed pollination season. Merely because grass hay fever occurs in the spring months and ragweed in the fall in the north, does not mean that high winds in winter cannot collect enough grass or ragweed pollen granules from building walls, parks, etc., to affect a hypersensitive pollen asthmatic. Only a knowledge of the pollen content of the air at the time and location of the inception of the allergic respiratory symptoms can answer that question, and may prove the real solution of the etiology of some of the northern socalled nonallergic or bacterial asthmas, as it apparently has with us.

The following case also is at least decidedly suggestive of a connection between the grasses and northern perennial asthma:

Case VI.—I. S., aged forty-eight, first seen December 21, 1921, occupation none for years on account of asthma starting in childhood in England. Had lived most of his life in Chicago and Los Angeles with almost daily severe chronic asthma; was

always a little worse in the fall, winter and spring. Had had no hay fever for years. His first skin tests were done at the clinic of Rush Medical College several years ago, with the diagnosis of food asthma. No improvement occurred from dietary restrictions. Our skin tests when first seen by us revealed strong positives to ragweed, feathers and various foods. On account of his having symptoms perennially, the pollen test was disregarded and he was considered a feather-animal hair-food case. Precautions along that line were instituted, together with an outdoor existence. He did very poorly requiring almost daily doses of adrenalin. He then returned to Chicago with several admissions to the Michael Reese and Augustana Hospitals, where he made no improvement in spite of a double cervical sympathectomy done at the latter hospital in the spring of 1924. He was then treated in Newark, N. J., and New York City by high class allergy workers and considered a house dust case. Treatment along this and other lines gave no results. During all this time he lived outdoors or with windows open as far as possible.

He returned to San Antonio in February, 1925, with his usual considerable asthma. The possibility of pollen influences were then considered as a last resort, and a strict closed window, indoor régime ordered. Much to our surprise immediate relief followed. Our only winter pollen consistent with his history was grass. Intradermal tests with various grasses were negative. He was then tested hypodermatically in the usual manner being negative to 0.05 c. c. of a 1:5,000 extract, but moderately positive (++) to 0.05 c. c. of a 1:500 extract.

He was then considered a grass case, and the indoor existence maintained. This patient has been practically entirely clear of asthma at this writing for five months, a far longer period of remission than he can remember ever previously occurring. He has been desensitized to the grasses using timothy extract, final dose being 0.3 c. c. of a 1:20 extract. He has taken no pollen precautions for a month, and remains without symptoms. Naturally a year's remission will be more conclusive.

In consideration of the fact that we failed in this same person four years ago at the same time of year and under apparently identical environmental conditions, except with regard to pollen precautions, with additional failures at the hands of some of our best allergy men who did not consider this possible grass etiology on account of the negative skin tests and perennial nonseasonal history, the result in this case is at least suggestive of the correctness of the present etiological diagnosis.

Be that as it may regarding other localities, of which, of course, we can say nothing, it is none the less the fact that since the recognition of this grass pollen agency as a common factor of hay fever and asthma, tests or no tests, and the immediate institution of a constant closed window, indoor régime, where possible to do so, we have not had but two cases of socalled nonallergic asthma in the past year fail to lose their asthma within a few days, whereas previously with fresh air régime, we had, like all other allergy workers, cases in hospitals for months at a stretch failing to clear in spite of the elimination of feathers, wool and other apparent antigens. We have not had sufficient experience to warrant drawing deductions as to the diagnostic value of the hypodermic tests with other antigens.

Of course, the permanent maintenance of such a closed, indoor existence in an impossibility and relapses occur when such régime is broken for one reason or other, hence the necessity for subsequent specific desensitization. In the desensitized grass cases quoted as successes, such precautions have been omitted for months, though carefully kept at first for many weeks until a high degree of protection had been secured.

The Use of Sodium Iodide Intravenously in Infections and Allergies

JAMES W. WILTSIE, M.D.,
Binghamton, N. Y.

(*Concluded from page 237*)

Case V.—A. P. entered my office complaining of heart trouble, dizziness and exhaustion. His appendix had been removed in October, 1924, during an acute attack. His tonsils were removed in July, 1925. A number of abscessed teeth had recently been extracted. There was one more under suspicion. The sockets of the recently extracted teeth were infected and discharging pus. His pulse, sitting, was 120, standing, 132. He had palpitation of the heart upon the least exertion. He had done no work in two and one-half months. His heart sounds were normal. His blood count showed 6,300 white cells, 64 per cent polys, 34.5 per cent lymphocytes. Sodium iodide was given intravenously. Next day the blood count showed 6,600 white cells, 78.5 per cent polymorphonuclears and 20 per cent lymphocytes. The suspected tooth was quite tender. His upper and lower gums were sore. He felt grippy and achy all over. The third day he felt better generally. His pulse, sitting, was 108. Another injection of iodide was given. The day following this he felt still better. He then had the suspected tooth extracted. It was found to abscessed. One week from the time he received the first injection of sodium iodide his pulse, sitting, was 92. He has continued to improve and is now well enough to go back to work.

CASE VI.—M. S. was losing a pound a week, was nervous, exhausted, had frequent headaches, and was toxic. Thorough examination revealed no apparent cause. Tonics, iron and arsenic intravenously and endocrine treatment were all valueless. After six injections of sodium iodide at two and three day intervals acute appendicitis developed. The appendix was removed and found to be full of pus. She is now well and vigorous and has gained nine pounds in weight.

CASE VII.—H. T. B., a business man, was completely run down in health. For four months he had been unable to do scarcely any work. At the time I saw him he was spending most of his time in bed. He complained of a constant pain over his heart, was nervous, exhausted, dizzy, apathetic and showed a steady loss in weight. He had been through the whole gamut of physical examinations by several physicians. No cause could be found to account for his condition. He did not respond to any therapeutic measure that had been tried. After an injection of sodium iodide he complained of a very sore throat lasting several hours. Following a second injection given two days later he again had a sore throat. This occurred again after a third and a fourth injection, but was progressively less marked each time. His tonsils were under suspicion and were removed. They were found to be deeply buried and badly infected. His general health improved at once.

A pain developed over McBurney's point, which he had never noticed before. We watched it. After four weeks of continued improvement, he again began to decline. Sodium iodide was again resorted to. He improved at once. After the fourth injection he did not feel as well. He felt still worse after the next two. Four days after the sixth injection an intravenous injection of iron and arsenic was given. Within one hour a severe pain developed over the appendix. The appendix was removed and found to be acutely inflamed. He is now steadily improving again in health and spending more time every day in his office.

ACTION OF IODIDE

I believe the iodide acted in dissolving exudate about the chronically infected appendix so that when the arsenic was given a dilatation of capillaries and lymphatics carried the infection into new territory.

In these last two cases the immunity developed was not sufficient to destroy the infection in the lymphatics of the appendix, and with the destruction of Nature's defensive barrier all that was necessary was some minor disturbance to cause an acute attack. In this cast case it was the arsenic. I have since had two additional cases of appendicitis, one developing in two weeks and one in two days after the use of sodium iodide, both acute in character, with vomiting, dizziness, pain, tenderness and all the classical local and general symptoms. All four of these cases were diagnosed clinically, no blood counts having been taken, but all were unmistakable, as verified by operation in each case and by subsequent complete restoration to health. I doubt if anyone would dispute me if I expressed my belief that blood counts in these cases would have shown a marked increase in leucocytosis.

In addition to these cases I have brought to light at least half a dozen cases of chronically infected tonsils, local reactions occurring in all but one, general reactions of a toxic, grippy nature in all of them, and an increase in leucocytosis whenever the blood counts were taken. Several cases of myositis have shown both local and general reactions with increased leucocytosis and have cleared up entirely under iodide therapy.

DIAGNOSTIC VALUE

As a result of the foregoing observations, I have adopted the use of sodium iodide intravenously as a diagnostic measure whenever chronic focal infections are suspected. I take a white and differential count before using iodide intravenously and again twenty-four hours later. I look for an increase in leucocytosis and for a local and general reaction. As a rule one or all of this trio are present. Sometimes one injection is all that is necessary for a diagnosis. Sometimes as many as six are required at intervals of two or three days. I rarely give more than six. Occasionally, after three or four injections, I give an intravenous injection of iron and arsenic, especially when an abdominal condition is suspected, as arsenic is known to have a dilating effect upon the mesenteric arterioles and capillaries. I rarely give injections of iodide on two consecutive days.

SYPHILIS AND TUBERCULOSIS

It is easy to see now why syphilis is benefited and tuberculosis made worse by the use of iodide. The exudates are absorbed in both cases. The lesions of tuberculosis are focal, and Nature's effort is to encapsulate and fibrose them. In her experience this is the best way to protect the organism against the ravages of the disease. In syphilis, however, the spirochete is everywhere, and Nature has developed a tolerance and has made no attempt to wall it off. The solution of exudates and pathological tissue is therefore of benefit in syphilis and a real detriment in tuberculosis. This holds also for the immunity reaction, as it is more difficult to produce an immunity against tuberculosis than it is against syphilis, and any immunity reaction if at all explosive is harmful in tuberculosis, causing an extension of lesions, but not so in syphilis. The supposed specificity of iodides in syphilis is merely apparent, as the pathology in syphilis is admirably adapted to give us a grandstand play of the therapeutic activity of iodides.

The appearance of a positive blood Wassermann reaction in spinal syphilis after the use of sodium iodide, where a negative Wassermann existed before, is a very pretty demonstration of the operation of sodium iodide in stimulating amboceptor elaboration by the release of antigens.

It must appear evident that the administration of sodium iodide would be contraindicated in any condition suggestive of tuberculosis, or for that matter in any condition in which a localization of infection is to be desired. In general it should not be used in acute conditions unless they are accompanied by a leucopenia.

ESTABLISHMENT OF IMMUNITY

In the foregoing cases we have been discussing the establishment of a true immunity in cases of in-

fections. In allergies we already have an immunity established to a high degree. Leucocytosis is already present as an expected accompaniment. We would naturally fail to see what beneficial effect an antigen liberator would have here. But the fact remains that allergies are benefited by sodium iodide intravenously, and that this benefit is accompanied by a drop in leucocytosis. Why should sodium iodide aid in establishing an immunity in the case of infections, and yet apparently destroy a high degree of immunity in allergies?

CASES OF ALLERGY

I have only a few cases of allergy in which I have taken white and differential blood counts before and after the administration of sodium iodide. Several of these cases are complicated with other conditions. However such cases as I have are rather suggestive if not conclusive. I have used sodium iodide in six cases of autumnal hay fever with marked relief in every case. I have had equally good results in at least as many cases of bronchial asthma. One case of eczema, apparently due to a metabolic insufficiency, showed an amelioration of all symptoms, the disappearance of edema and a drop of leucocytosis from 14,200 to 8,600 in three days, following two injections of sodium iodide. One case of urticaria and one showing gastric disturbances of unrecognized origin both yielded to sodium iodide with an accompanying drop in leucocytosis and polymorphonuclears.

Case VIII.—E. W. had suffered for years with hay fever and asthma. She entered my office suffering from an unusually acute attack of autumnal hay fever. Her blood count showed 13,200 white cells, 72 per cent polymorphonuclears, and 24 per cent lymphocytes. I gave her an injection of sodium iodide intravenously. She slept that night for the first time in some days. Next morning she had practically no indications of her hay fever left. Eighteen hours after the sodium iodide had been given, I took another blood count. It showed 8,400 white cells, 69 per cent polymorphonuclears, and 28.5 per cent lymphocytes.

Case IX.—Mr. T., suffering acutely with hay fever, but also showing a four plus Wassermann reaction and complaining of a splitting headache, was relieved of his headache instantaneously and his hay fever by the next morning by one injection of sodium iodide. His white cell count was 10,600 before and after the injection. His polymorphonuclear count dropped from 55 per cent to 53 per cent in twenty-four hours.

Case X.—Mrs. C., suffering from hay fever, complicated with myositis and a possibly chronically infected gallbladder, which I have judicially disregarded and have not attempted to follow up as I do not believe her in any condition to undergo an operation at this time, showed immediate relief from her hay fever after one injection of sodium iodide. Her white count before the administration of iodide was: white cells, 5,300, polymorphonuclears 64.5 per cent, lymphocytes 33 per cent; twenty-four hours later it showed 5,200 white cells, 69 per cent polymorphonuclears and 29.5 per cent lymphocytes. Six days after the iodide it showed 3,400 white cells, 62 per cent polymorphonuclears, 35.5 lymphocytes. I then gave one more injection of iodide and took a blood count next day. It showed 5,000 white cells, 50 per cent polymorphonuclears, and 47 per cent lymphocytes. After the first injection of iodide she showed a rather marked general reaction with nausea and vomiting lasting nearly all night. There was considerable tenderness on right side below the ribs. She complained of being dizzy for three or four days following. After the second injection, these symptoms were all lacking. Three weeks after the first injection she was feeling in better general health than she had for months past.

In dealing with allergies we are dealing with highly sensitive overstimulated amboceptor elaborators. To attempt to stimulate immunity here would be to whip an already overworked cell.

CELLULAR THEORY

According to the cellular theory of allergies, desensitization is brought about by changing the colloid arrangement within the sensitized cell so that it ceases to perform its immunity function. This condition has been brought about accidentally in true immunity in a few cases where the immunity had been built up to a very high degree artificially by still further injection of the specific antigen. It is commonly done in specific desensitization of hay fever by pollen inoculations, and in other allergies by inoculation of the specific antigen whenever it can be determined. Recently desensitization has been brought about by the use of nonspecific substances such as proteoses, peptone and sodium chloride injected either intramuscularly or intravenously. I believe the results obtained by the use of sodium iodide in allergies are due both to its action as a nonspecific desensitizer by overstimulating directly an already overworked cell function (i.e., by virtue of a primary action of the iodine ion), and also by specific stimulation of the function of amboceptor elaboration, i.e., by virtue of its action in suddenly releasing a flood of specific antigens from edematous areas and pathological exudates into the blood stream, thereby permitting them also to act upon the sensitized cell. The result is a sudden collapse or exhaustion of the immunity function as a result of cumulative stimulation, having possibly as its physical basis a rearrangement of the intracellular colloids. Thereafter the elaboration of specific amboceptors ceases—a necessary factor in the fixation of complement is missing, and consequently we have no toxic end product to produce the symptoms of anaphylaxis or allergy. This would explain way a person recovering from a severe anaphylactic shock is able to tolerate large doses of the very antigen that originally produced the shock. With the absence of complement fixation the demand for a leucocytosis ceases, and our leucocytosis falls. This, then, is the solution of our paradox.

USE DURING ACUTE ATTACK

It can be better understood now why sodium iodide is beneficial only when used during an acute attack of an allergic condition, and why the benefit is greater in the severest cases. We must have the effect of overstimulation added to an already overworked cell function, the more nearly exhausted the function, and the stronger and more nearly specific the added stimulation, the more complete and permanent is the relief.

The Inheritance and the Medicolegal Application of the Blood Group

J. ARTHUR BUCHANAN, M.D., M.S.
Brooklyn, N. Y.

The medicolegal application of the blood group is surrounded with difficulties because of the transmission between generations by the germ plasm of the unit factor upon which a blood group depends. There is a total inability at present to tell whether a person is homozygous or heterozygous for the blood groups by a study of the blood group as it appears in the blood stream. All of the evidence available at the present time points to the four blood groups being hereditary.

The groups referred to in this paper are classified according to Jansky (1), although I used the Moss (2) classification in my work.

BLOOD GROUP FOR DETERMINING PARENTAGE

The use of the blood group as a means of determining parentage was first recommended in absolute terms by Ottenberg (3), although its possible use had been suggested or suspected prior to his recommendations. His conception of the hereditary nature of the blood group rests on a study of a portion of the elements upon which blood group is supposed to depend, namely the isoagglutinogens (A and B) of the red blood cells. The isoagglutinins (a and b) of the serum were ignored except to state that they were recessive to the agglutinogens. From a genetic viewpoint he, as well as others, believes that Group II and Group III each consists of a dominant and a recessive character, and that Group I and Group IV consist of recessive and dominant characters respectively. The rules of Ottenberg concerning parentage centre about his believing that unless the dominant substances are present in the parents they cannot appear in the children; and that Group I is a pure recessive, so that from crosses of Group I only Group I children could result. Ottenberg reports three crosses of Group I and Group I that are of conclusive value.

The conceptions of Ottenberg of the biological nature of the blood groups are perhaps best shown in the analysis of families in which crosses of parents in Group IV and I bear children in Groups II and III. It appears that Ottenberg believes that the specific substances for blood group rearrange themselves in the germ plasm of the parents, so that the agglutinins of Group I separate and recombine with the supposed dominant substances of Group IV, and after a recombination give blood Group II and III in the blood stream of the zygotes. There is no evidence to substantiate such a conception, although crossing over of chromosomes may be imagined in such instances. As crossing over does not explain some of the other data in connection with the blood group, it probably does not occur at all in connection with the germ plasm changes that take place in such crosses in order to produce the blood group of the zygote. There are rules governing the theory of crossing over. If crossing over occurred in the family reported by Ottenberg, it should occur in all similar crosses, and as there are families on record in which crosses of Group IV and Group I resulted in children in only Group IV and Group I, the crossing over of chromosomes can not explain the findings in families in which the children are in groups different from the groups of the parents.

Ottenberg believes that it is possible to foretell a parent in certain families by grouping one parent and the children. This belief arises from the dictum concerning the dominant substances. It is frequently possible to predict what the other parent might be without believing in the socalled dominant substances. The prediction will often be verified, but not because of the truthfulness of the theory that dominant substances must be in the blood stream of either parent. The danger of going wrong in such predictions rests in the possibility that a parent might be a heterozygote crossed with a homozygote, and only children with the blood group of the homozygote and the dormant character of the heterozygote appear. A subsequent crossing of these children would show unexpected blood groups. The necessity of actually knowing the ancestry in a pedigree study has been worked out in cattle by Cole and Jones (4).

The germ plasm constitution of homozygotes and heterozygotes for the four blood groups. The agglutinogens (A.B.) and agglutinins (a.b.) do not behave as unit characters.*

Egg or Sperm Gametes

Sperm or Egg Gametes	AB (IV)	Ab (II)	Ba (III)	ab (I)
AB (IV)	(IV) AB AB (IV) X	(II) Ab AB (IV)	(III) Ba AB (IV)	(I) ab AB (IV)
Ab (II)	(IV) AB Ab (II)	(II) Ab Ab (II) X	(III) Ba Ab (II)	(I) ab Ab (II)
Ba (III)	(IV) AB Ba (III)	(II) Ab Ba (III)	(III) Ba Ba (III) X	(I) ab Ba (III)
ab (I)	(IV) AB ab (I)	(II) Ab ab (I)	(III) Ba ab (I)	(I) ab ab (I) X

*The blood group in the blood stream of the zygote is theoretically represented on the right, although the one on the left might appear in any of the crosses. There is no way of predicting in crosses, whether the group of the male or female is most likely to appear first in the offspring. The reversibility of the blood groups in the heterozygotes is shown.

The rules of Ottenberg are formulated from the study of families which are too small in most instances to determine even partially the breeding possibilities of either parent, and without investigation of more than two generations. It is quite unlikely that an animal breeder would conclude from a two generation study that an animal was pure bred, and that only pure types would appear among its offspring.

DATA OF OTTENBERG

Of the families reported by Ottenberg I consider the third, fifth, seventh, twenty-second, twenty-ninth, fortieth, forty-sixth, and fiftieth as satisfactory for measuring, at least partially, the breeding possibilities of the parents. I consider the twenty-eighth, thirty-third, thirty-fourth, sixty-fourth, and sixty-sixth families of some value so far as numbers are con-

cerned. Small families of father, mother, and one or two offspring are largely valueless in this study. It is impossible to tell what the next child might be if only one child in a family is studied. I could have included in my studies a large number of such instances if I had been willing to accept such meagre criteria to prove a difficult problem of genetics. Small families are of value, however, in showing the possible groups from certain crosses. In fact, observations on parents with one child first called my attention to the fact that Group I parents could have legitimate children in a group other than Group I.

METHOD USED IN MY WORK

I used the technic of Vincent (5) in my work (6). The microscope, however, was used in all instances to confirm the macroscopic findings. The ten sources of error mentioned by Ottenberg did not enter into my work. Another rare source of error not mentioned by Ottenberg is the hemolysis of red blood cells in 2.5 per cent. sodium citrate solution. In the instances in my work in which this occurred the cells were discarded and fresh cells obtained. The work was repeated in the instances in which data at variance with the statements made by Ottenberg as to the breeding possibilities of parents were obtained. The cells in practically all of the families were checked with homologous sera. Fresh sera were used at all times.

In all of the families studied by myself not only was the mother informed as to the nature of the investigation, but the father also. In no family was there a question of illegitimacy. There was no reluctance on the part of the parents to have the work carried out. In the instance in the Tink family in which the criteria of Ottenberg were overturned, the cells were regrouped. The specimen was delivered to me with new markings, and in the midst of new specimens, so that I did not know that I was repeating the work until after the grouping was completed. The family had been thoroughly studied previously, as to family characteristics, by an institution well qualified to make such an investigation. Many of the known physical characteristics that are hereditary have been worked out in the family. A question of illegitimacy has never arisen.

SIGNIFICANCE OF MENDEL'S DISCOVERY

The essential discovery of Mendel was that in the germ plasm of hybrids, a segregation of the unit factors occurs. The unit characters of zygotes depend upon unit factors. The elements of dominance and recessiveness formed a mere subsidiary discovery. They were often important but never essential in the establishment of the transmission of a character by the germ plasm. The combination of a dominant and recessive character in the same zygote constituted a hybrid. Mendel worked with characters which he arbitrarily designated by some symbol for purposes of distinction. He used the capital letters of the alphabet to denote dominant characters and the small letters of the alphabet to denote recessive characters. Mendel primarily described all hereditary characters as constants, and gave them working formulas, which in their integrity were unvariable.

In attempting to prove the inheritance of any character in man the assumption of fixity as to the nature of the character to be studied is essential. The fundamental difference between studies in heredity in man and the lower animals and plants is the absence of a hybrid stage, or the stage of the first filial generation. In crosses in man there is an immediate progression to the separation of the characters of the parents, so that they appear in the first generation of the offspring, provided a sufficiently large number of children result to permit of this. Dominance and recessiveness derive their significance from the first filial generation and since this generation is absent in man, they can have no definite significance in the terminology for studies of heredity in man.

The characteristics of hybrids were studied by Kölreuter (7) years before Mendel. Mendel simply mated hybrids, and noted the appearance of the characters of the parental stem together with the same type of hybrid. I use the term hybrid to designate the offspring resulting from the first cross of pure types, and heterozygote for mixed individuals occurring in all subsequent generations, although biologically a hybrid and a heterozygote are the same.

CORRELATION OF LABORATORY AND GENETIC DATA

The blood groups are considered to be due to the presence in the red cells of agglutinogens (A. B.), and to the presence of agglutinins (*a. b.*) in the serum. The material entities, upon which blood group depends, are entirely unknown. The existence of these specific substances has been supposed because of laboratory experiments. The genetic study of the blood group, however, has been confined to the agglutinogens.

Any attempt to explain the inheritance of the blood group without studying the blood group as a whole ignores one half of the problem. If one half of the blood group is hereditary, the other must be. If the blood group is hereditary there is no possibility of additional agglutinins appearing in the blood stream unless the ancestry is such as to permit of this. According to this conception it is impossible to get a Group I offspring from Group II parentage. There is no possibility of introducing from any source into the blood stream the factor upon which the second agglutinin depends for its existence. It is quite easy, however, to understand this occurrence when it is known that there is a Group I grandparent in the family, and that one of the parents has a mixed germ plasm constitution for blood group. The fourth, fifty-second, and sixty-second families of Ottenberg would be clarified by a review of the grandparents in each instance.

The theoretical agglutinins and agglutinogens are so arranged in the blood stream of man as to give the four blood groups, I, II, III, and IV. By using symbols for the agglutinins and agglutinogens the groups have been expressed as *ab* (I), A*b* (II), B*a* (III), and AB (IV). While *a* and *b* have been used to designate the absence of agglutinogens, they are used to designate agglutinins, an actual character present, so that although they represent the absence of one character, they represent the presence of another. The occurrence of a white chicken from black ones never results unless there has been a white chicken mixed up in the ancestry.

(*To be continued*)

Diagnosis and Treatment of Seasonal Hay Fever*

AARON BROWN, M.D.
New York

HISTORICAL

The first true description of hay fever as a clinical entity was given by John Bostock (1) in 1819. He ascribed the seasonal condition to external irritants, dust, bright lights, heat, and special odors.

In 1831, Elliotson (2), another Englishman, suggested that hay fever was due to the blossoms of graminaceous plants; but it was Blackley (3) in 1873, who properly described hay fever and established pollens as the cause.

In 1903 Dunbar (4) elaborated on Blackley's work and proved that the element in the pollen responsible for the symptoms was associated with the protein. However, recent researches at the New York Hospital, by Grove and Coca (5), have shown that the active principle in the pollen is not a true protein. They removed all protein and other detectable nitrogenous substances from pollen extracts, by means of tryptic digestion and dialysis and found no appreciable lessening in the atopic activity of the extracts. The active principle of the pollen is, therefore, not a protein in the usual sense.

Prausnitz and Kuster (6) have demonstrated specifically reacting substances in the blood of hay fever subjects, which have now proved to be responsible for the hypersensitive condition. It has been suggested that the term reagin be applied to designate this specific reacting body in the blood.

Researches at the New York Hospital by Levine and Coca (7) have shown that the degree of sensitiveness is dependent upon the concentration of these blood borne substances (reagins), and this concentration of the reagins in any atopic serum, can be measured with the use of the passively sensitized site.

SEASONAL HAY FEVER

Seasonal hay fever affects about one per cent. of the white population of the United States. The sexes are about equally affected, with a slight preponderance among females. It may occur at any age, but is most frequent between the ages of twenty and forty. It lasts years, often being so mild as to escape attention for a long time.

Seasonal hay fever requires, first, a predisposition, an inherited tendency, and secondly, an exciting cause, the pollens.

The inherited tendency of hay fever was demonstrated by Cooke and Vander Veer (8). This tendency is inherited most probably, as a Mendelian dominant, and may appear in a number of clinical forms, asthma, hay fever, urticaria, etc. These authors have also brought out the fact, that the stronger the hereditary factor, the earlier is the age of onset of symptoms. Atopic symptoms appear before the tenth year in seventy-three per cent. of children with a bilateral family history, as against nineteen per cent. where the antecedent history is negative.

*Paper read before the N. Y. Physicians Association, May 28th, 1925. From the Dept. of Immunology Cornell University Medical School and the New York Hospital.

The pollen is the fertilizing agent of plants and is analogous to the spermatazoon in animals. Perfect flowers produce their own pollen, but most flowers are imperfect, and pollen must be carried for considerable distances to reach the pistils of plants. Pollen grains vary in size, color and shape. The smallest grain is six micra, the largest 280 micra in diameter. Pollen is usually yellowish but may be any color. It is most often spherical in shape. Chemically, pollen contains about twenty-five per cent. of protein. Pollen is disseminated either through the air, or by insects. When wind pollinated, flowers are inconspicuous and pollen is profuse. Insect pollinated flowers are bright colored or white, sweet smelling, and the pollen is scanty in amount.

Practically speaking, only pollens that are air borne are factors in the causation of seasonal hay fever. Insect pollinated plants only affect by direct contact, and therefore are of very little importance. Goldenrod (solidago canadensis), daisy (chrysanthemum), dandelion (leontodon), roses (rosaceae), sunflower (helianthus), clover (trifolium), and the fruit trees are insect pollinated.

SYMPTOMS OF SEASONAL HAY FEVER

The annual attack of seasonal hay fever occurs in accordance with susceptibility and exposure to pollens. There is tickling in the eyes and nose with tearing and sneezing. The nasal mucous membrane becomes edematous resulting in a copious discharge of serous fluid. A symptom often present and bitterly complained of, is the tickling sensation in the soft palate and posterior nares. Often there is an attack of asthma.

These symptoms may be mild, and confined to a particular mucous membrane, eyes, nose, throat or bronchi. If the symptoms are severe, malaise, general irritability and digestive disturbances may be present. These symptoms continue with various degrees of severity, depending upon weather conditions during the season, with aggravation of symptoms on hot, dry and windy days, and marked relief on rainy days. All symptoms stops when pollen ceases to form. Hay fever is, of course, neither contagious nor infectious.

TREATMENT

The present day treatment of seasonal hay fever is based on the principle of desensitization of animals, introduced by Besredka. He found that sensitive animal could always be rendered specifically and completely insensitive, by a suitable and gradual neutralization of antibodies which are responsible for the hypersensitiveness (desensitization). In 1911 Freeman (9) and Noon (10), in England, and Robert A. Cooke (11), in this country, made successful use of this concept in the treatment of hay fever.

It is immaterial to the patient, whether the process involved is that of actual desensitization or not, he is concerned only with the results obtained. As a matter of fact, the process is not that of desensitization, for we must distinguish between anaphylaxis

or animal hypersensitiveness, and atopy or inherited hypersensitiveness in human beings. In brief, some of the differences between the two are:

VARIATIONS

1. In anaphylaxis the exciting agent is antigenic (capable of producing specific antibodies); in atopy, the existing agent is often not antigenic; it may be a drug. No specific antibodies are produced.

2. Anaphylaxis requires two injections, one to sensitize and the second to shock; in atopy, first contact often is sufficient.

3. Anaphylaxis is artificially produced; atopy is inherited.

4. In anaphylaxis complete desensitization is always successful; not so in atopy. Positive skin reactions persist, though they may be modified. A small dose of a specific protein, has been known to stop all symptoms of hay fever for years. This is unknown in anaphylaxis. In fact, after a time, the animal becomes more sensitive.

What we produce by treatment is a lessened clinical sensitiveness, a hyposensitization.

VARIETIES OF SEASONAL HAY FEVER

There are two principal varieties of seasonal hay fever in this section of the country: the early, or spring type, and the late, or fall type.

The early variety (March to July) is usually due to the pollens of the grasses (gramineae), timothy grass (Phleum pratense), June grass (Poa pratensis), orchard grass (Dactylis glomerata), red top (Agrostis vulgaris), corn (Zea mays), and plaintain (Plantaginaceae), etc.

The tree pollens are sometimes factors at this time of the year. The fruit trees are insect pollinated and therefore can be disregarded, but tests must be made for the ash (Fraxinus americana), hickory (Hicoria ovata), oak (Quercus varieties), maple (Acer varieties), elm (Ulmus americana), poplar (Populus), birch (Betule varieties), and pine (Pinus varieties), which are wind pollinated, especially if the hay fever starts in March or April. Trees, however, pollinate for a short period, two to three weeks, and fortunately affect only a small number of persons.

Grasses are biologically identical and show a group reaction. Desensitization with timothy grass, the most important members of the group, protects completely against the other grasses. Clinically, we have treated a series of patients (early hay fever subjects), with timothy grass extract; another series with timothy and orchard grass extracts, and still another series with the combined extracts of four grasses, and we obtained just as good results with timothy alone as with any other combination. This clinical experience has been substantiated in the laboratory by the recent work of Coca and Grove (12), who, by means of passive transfer, have proved that all of the atopins of June grass, orchard grass, and red top, are contained in timothy pollen. Plantain must be considered as a separate factor, and is responsible for a small percentage of early cases.

FALL TYPE OF HAY FEVER

The late or fall type of seasonal hay fever is due principally to the common ragweeds (Ambrosia elatior and trifida), the season extending from August 12th, or thereabout to the first frost. The majority of patients are symptom free by September 15th.

DIAGNOSIS

The diagnosis of seasonal hay fever is made by 1, the history, abrupt onset, annual recurrence, abrupt cessation; 2, tests with extracts of the suspected pollens. The tests are the skin and eye tests.

TESTS

Skin Tests.—It is common knowledge that the skin almost always carries cells that are hypersensitive to the same substance that affects the nasal, bronchial or conjunctival mucous membrane. We, therefore, happily, have a most excellent means for specific diagnosis.

There are two methods of testing the skin; the dermal or scratch test, and the intradermal or intracutaneous test. In the scratch test, a small amount of the extract is applied to a linear scratch in the skin; in the intradermal, one hundredth or one fiftieth of the solution is introduced into the layers of the skin, by means of a tuberculosis syringe, using a 26 or 27 gauge needle.

In either test, a positive reaction is determined by the formation of a wheal, with pseudopod projections. Reactions (wheals) one, two or three centimeters in diameter, are designated one, two or three plus, respectively.

There can be no question that the intradermal test is much better (13). Its advantages are: 1. It is easier to perform. 2. Less time is required. 3. It is more convenient, the same solution being used for testing as for treatment. 4. It has a greater diagnostic accuracy. Intradermal reactions are read in from five to ten minutes.

Ophthalmic or Eye Test.—A drop of the pollen solution in instilled into the conjunctival sac, with the same syringe used in performing the intradermal test, and a positive reaction is determined by the resulting circumcorneal and conjunctival injection, with itching and tearing. Reactions are noted one, two or three plus, depending upon the degree of conjunctival irritation. Reactions are read within five minutes. In the eye test, the reaction depends upon the concentration and not upon the amount of the solution instilled.

The eye test is of extreme importance. We are interested in mucous membrane sensitivity, and the conjunctiva is a most convenient mucous membrane, and enables us to reproduce in minature, the seasonal condition.

CLASSIFICATION OF CASES

Having determined that the mucous membrane is sensitive, we now go back to the skin and classify our cases, in accordance with reactions to the various strength solutions used.

Our pollens are extracted with Coca's (14) fluid, and standardized by their nitrogen content. Levine and Coca (15) have shown that, prepared as described above, the nitrogen content runs parallel with the atopin content of the pollen extract.

The test solutions used contain .0001 mg. nitrogen to the c.c., .001 mg. nitrogen to the c.c., .01 mg. nitrogen to the c.c., and .1 mg. nitrogen to the c.c.

Cases are classified A, B, C or D according as

they react to the first, second, third or fourth of these dilutions. Patients may fall in between these classes and be AB, BC or CD.

Class A patients, which are the most sensitive, require a comparatively small amount of pollen extract to protect them, the maximum dose reached being equivalent to .01 mg. nitrogen to the c.c. Class B patients are less sensitive and require more extract, reaching a maximum dose equivalent to .025 mg. nitrogen to the c.c. Class C patients reach a maximum dose of .06 mg. nitrogen to the c.c., and Class D patients, the least sensitive, require a comparatively large amount of extract, reaching the maximum dose of .1 mg. nitrogen to the c.c. Most patients fall in class B or C.

It is best to begin treatment preseasonally, starting our injections eight to ten weeks prior to the date of expected onset, giving treatment at weekly intervals. The strength of the pollen injections are gradually increased, according to a fairly definite schedule, to reach the maximum dose in the class (A, B, C, D), at about the time of the onset of the season. Injections are continued *throughout the season,* at seven to ten day intervals, the number of injections given to a patient numbering about twenty.

CONSTITUTIONAL REACTIONS

These occur about once in every two hundred injections and are manifested by the appearance of hay fever, urticaria or asthma. If the reaction is severe all three types are present. Constitutional reactions usually occur within an hour after the injection and are readily controlled by giving six to eight minims of adrenalin hypodermically.

Constitutional reactions are due to the following causes:

1. Injection of extract into a vein. Reaction here is almost immediate, but may be prevented by detaching syringe from needle, to see if blood flows.

2. Changing the extract. Fresh extracts are more potent. In changing from an old to a fresh extract, the patient is likely to get an overdose. We prevent this by making up all the extract for the season's use at one time. Secondly, we keep the extract on ice. Under these conditions the extract maintains its full potency for at least a year.

3. Overdoses. Carefully classifying our cases, and controlling the dose by keeping to schedule, will prevent constitutional reactions from this source.

MULTIPLE REACTIONS

Where the patient is sensitive to more than one pollen, not biologically related, each pollen is to be used as a distinct entity.

Patients should be tested, not only with the suspected pollens, but also with some of the inhalants, especially house dust, and where marked reactions to house dust occur, it is advisable to add dust extract to the pollen injections.

All early cases should be tested with ragweed and all late cases with timothy extract, because patients sometime show skin sensitivity, before mucous membrane sensitivity develops, and while we treat only clinical manifestations, still it is important to keep a record and warn patients in advance.

Early hay fever is about one quarter as frequent as the late form, but many patients have both forms associated. Forty per cent. of patients have asthma as a complication. This type of asthma requires no special treatment and is usually well controlled by the pollen injections.

SEASONAL TREATMENT

Treatment of patients, who present themselves after onset of symptoms, is advisable, although it does not offer the same promise of good results as preseasonal treatment does.

Cases are classified as above, the eye tests being omitted. Doses are small, injections being given daily, or on alternate days, with a view of enhancing the patient's immunity as rapidly as possible. In about fifty per cent. of the seasonal cases the patients do well under treatment.

DRUGS

The following prescription will be found useful during the season. These eye drops may be used freely. One or two drops being instilled into each lower eyelid controls not only the eye irritation but also helps the nasal symptoms.

Cocainæ Hydrochloridi	gr. 1
Adrenalin Chloridi (1-1000)	℥ 1
Acidi Boric	gr. XX
Aq. Rosæ q. s. ad	℥ 1

The preseasonal treatment of hay fever offers the best opportunity for relief to the patient. In general we can offer some measure of relief to over ninety per cent. of our patients; about twenty-five per cent. are entirely relieved; about fifty per cent. moderately helped, and in only about five per cent. of our cases are we at the present time unable to be of any aid.

Instruments, Apparatus, and Clinical Notes

The Value of the Duodenal Tube to the Surgeon in the Postoperative Treatment of Certain Cases of Gastroenterostomy*

WILLY MEYER, M.D.
New York

Remembering that "to save life" is the primary aim of the calling of the medical man, the following observation deserves recording:

Case I.—S. G., female, thirty-eight years old, had complained of gastric disturbance for the last five years. A number of specialists had been consulted. Proper diet with internal medication, and later regular stomach lavage done by herself, kept her alive. In May, 1924, she came under the care of Dr. Einhorn. The radiograph (Fig. 1) best explains the status: typical hourglass stomach, complicated by a tight pyloric stenosis. The gastric constriction was situated about midway between cardia and pylorus, dividing the stomach into two pouches of almost equal size. The proximal pouch shows no six hour residue of the barium meal, the distal emptied slowly (Fig. 2). The patient had lost steadily, weighing now eighty-four pounds, but continued to do light work in her mistress's home—the latter, as well as the other members of the family had been friends to her rather than employers.

Fig. 1.—Typical hourglass stomach with pylorostenosis.

Fig. 2.—Slow emptying of distal portion.

Operation, the only procedure that promised hope for relief, was clearly indicated.

On May 2, 1924, the abdomen was opened under gas oxygen anesthesia. The stomach appeared as seen in the x ray films; it was extremely anemic and thin throughout. The stricture, midway, was of cicatricial character, evidently the result of a peptic ulcer. A second benign stricture involved the pylorus. In view of the normal emptying of the cardiac pouch and the marked stenosis of the pylorus, typical posterior gastroenterostomy was done between the distal pouch and the jejunum; short loop, needle and thread. At the completion of the suturing, and although no blood whatever had been lost and only oxygen used throughout the intraabdominal work which had been hurried as much as feasible, the patient's general condition forbade the immediate addition of the planned gastrogastrostomy. The parietal wound was quickly sutured and the patient returned to her bed. stimulated by hypodermic injections, rectal instillations, etc.

The first days passed comparatively satisfactorily, there was hardly any antiperistalsis. On the fourth day after the operation, with increase of intake and with rectal temperature at or below 100°, uncontrollable vomiting set in. Medication, gastric and colonic lavage brought no relief. Some tea was retained, but as soon as any nourishing liquids entered the stomach they were promptly rejected. After a few days of watchful waiting jejunal feeding or jejunostomy was

NEW YORK, WEDNESDAY, MARCH 3, 1926

Further Observations on the Treatment of Neurosyphilis with Tryparsamide

PAUL A. O'LEARY, M.D.
and S. WILLIAM BECKER, M.D.
Rochester, Minnesota

In June, 1924, Stokes and Wilhelm reported the first eighteen months' experience with tryparsamide in the treatment of patients with neurosyphilis and nonsyphilitic diseases of the nervous system at the Mayo Clinic. We have carried on the observation and treatment of the same group of patients except that those with advanced paresis, who were treated while inmates in the Rochester State Hospital, have been excluded, and that seventy-five patients who were started on treatment with tryparsamide since June, 1924, have been included. Altogether we have treated 207 patients with tryparsamide, but as this clinical and serological study is limited to those who have received at least two full courses (twenty injections) of the drug, only 113 of the case histories are reviewed.

In the previous report Stokes and Wilhelm classified the patients into six groups; we have added a seventh. They are as follows: 1, early general paralysis, confirmed by clinical and serological observation; 2, paresis sine paresi of Solomon, or asymptomatic paresis of Lorenz and Loevenhart; 3, tabes dorsalis without gastric crises; 4, tabes dorsalis with gastric crises; 5, congenital neurosyphilis; 6, nonsyphilitic diseases of the nervous system, such as multiple sclerosis, and 7, unclassified forms of symptomatic neurosyphilis. It should be emphasized at this point that the patients classified in Group 1 were in the early clinical phases of general paralysis. With few exceptions none of the patients was sufficiently advanced to warrant institutional care and in most instances the diagnosis made at the first examination was confirmed while intensive treatment with arsphenamine and mercury was being given. Group 2 includes patients who showed no clinical signs of general paralysis but whose spinal fluid remained persistently positive in spite of intensive treatment. Practically all of this group had persistent first zone colloidal benzoin reactions. The remaining groups are selfexplanatory.

The evaluation of a new drug or method of treating the parenchymatous form of neurosyphilis must not be based on serological changes alone. In fact, in this form of neurosyphilis improvement in the clinical signs of the disease is of more significance than serological reversals. The reports (2, 3) from the Mayo Clinic have called attention to the fact that clinical improvement in cases of symptomatic neurosyphilis is not always paralleled by serological improvement and, that serological reversal to normal is not always followed by clinical improvement. Wile and Wieder have also called attention to this point. We are not justified in seeking changes in the objective signs of this phase of the disease.

In this study evidence of clinical improvement was based on the somatic changes; improvement or disappearance of chief complaint; the mental improvement estimated by employer, family and neuropsychiatrists; restoration of earning capacity; restoration of personality; changes in personal appearance, and gain in physical strength and weight. The serological results were estimated both separately and in conjunction with the clinical results. The reversal of the Kolmer, Nonne globulin test, cell count and the colloidal benzoin to normal or negative, was considered "reversal to normal." If the pleocytosis was reduced to the point where the number of lymphocytes was normal and the Kolmer reaction reduced to a weak positive the condition was considered as improved. The changes in the Nonne and colloidal benzoin were not estimated. The tryparsamide was given in courses of ten injections each, from one to three gm. being administered at weekly intervals in conjunction with potassium bismuth tartrate with butyn, 0.2 gm. every five days, or mercury succinimid one sixth to one quarter grain five times a week for six weeks, or mercury salicylate one to two grains once a week. If the interval between the tryparsamide courses was two months or less no treatment was given between courses; if greater than two months, mercury rubs were given.

Group 1.—Of the fifty patients with early general paralysis treated with tryparsamide twelve per cent. showed a definite remission, sixty-six per cent. im-

proved in one or more ways, and twenty per cent. showed a reversal of the spinal fluid reactions to normal. Thirty-two per cent. showed improvement in the condition of the spinal fluid and sixteen per cent. a reversal of the blood Kolmer reaction to negative (tabulation). This estimate of clinical improvement is based on subjective improvement noted by clinical observation or reported by the patient's relatives or home physician, and it is not to be construed as clinical cure. The estimate of improvement has been arrived at in some instances by the disappearance of a single symptom, in others of multiple symptoms, and the reader should bear in mind that clinical improvement means subjective improvement. The clinical cures or complete remissions in this same group are estimated at twelve per cent., a figure which approximates the majority of estimated spontaneous remissions in cases of general paralysis (from four to twenty-one per cent., average of eleven per cent. from seventeen reports in the literature).

Solomon and Viets have recently called attention to the point that the greater the number of injections of tryparsamide the better are the serological results. Our study confirms this observation, in that patients who received the greatest amount of treatment responded better serologically. Of eleven patients in the group who had been intensively treated with slight benefit by arsphenamine intravenously, intraspinal medication, and mercury and iodids before receiving tryparsamide, five showed decided serological and clinical improvement after the tryparsamide, indicating that tryparsamide would sometimes accomplish results when routine measures fail. On the other hand, of thirty-five patients who had received practically no antisyphilitic treatment previous to the administration of tryparsamide, only five responded favorably to the drug. From these results it would seem that in a certain group of patients with parenchymatous neurosyphilis tryparsamide is beneficial as a "finishing off" form of treatment, but we know of no means of selecting, before hand, the patients who will respond well to tryparsamide.

Group 2.—Fifteen patients with asymptomatic paresis were treated intensively with the usual measures, but their spinal fluid and blood serum remained persistently positive, which suggested incipient parenchymatous degeneration. There were no clinical symptoms of paresis in any members of this group. In one case there was complete reversal of the spinal fluid reaction to negative, one patient was decidedly improved, and eight others had gained weight and were in better condition to carry on their occupations. In brief, more than half of the group manifested the tonic effects of the drug, a point which has been noted previously. In only one case was there serological reversal to normal. The blood Kolmer reaction became negative in four cases and was unchanged in the remaining eleven.

Group 3.—Fourteen patients with tabes dorsalis were treated with discouraging results. These patients were divided into two groups; those who had received the usual intensive treatment but who did not respond clinically, and those with advanced disease in whom symptomatic improvement only was sought. One of the patients who had previously been given the usual intensive treatment showed decided benefit from the tryparsamide course; there was complete reversal of the reaction of fluid and decided clinical improvement. Six others were improved serologically and two were somewhat benefited clinically. There were no significant changes in the Kolmer reaction of the blood.

Group 4.—Stokes and Wilhelm called attention to the possible value of tryparsamide in the treatment of tabes dorsalis complicated by gastric crises. Case 6, in their report, is the outstanding example of the effect of this drug in this condition. The patient had been treated energetically for six years by intensive methods with no improvement. Following the first course of tryparsamide there was a complete cessation of the crises for ten months; during this time he received two more courses. Since the relapse of the crises the continued use of tryparsamide made the severity and frequency of the attacks less than it was before the drug was used. Two other members of this group of eleven patients were slightly benefited, the intervals between attacks becoming longer and the duration of the attacks shorter and less severe. In one case there was a complete reversal of the spinal fluid reactions to normal, but no improvement was noted in the gastric crises. In another there was a reversal of the Kolmer reaction on the blood from positive to negative without symptomatic improvement. It is to be regretted that the promise offered by Case 6 in the report of Stokes and Wilhelm has not been duplicated in any others in this group. All these patients had the usual form of intensive treatment before receiving tryparsamide.

Group 5.—Six children with congenital neurosyphilis were treated; five had paresis, and one tabes dorsalis with gastric crises. Two of the group were slightly improved symptomatically, particularly in that they were more easily managed by their parents, and two showed serological improvement.

Group 6.—The fourteen patients in the nonspecific group having multiple or combined sclerosis and two with erythema induratum were not benefited beyond slight gain in weight.

Group 7.—In this group are included seventeen patients with undifferentiated types of syphilis of the central nervous system of whom an anatomic classification is not as yet justified. In some of these cases the symptoms bordered on those of asymptomatic paresis while other cases were included because of continued relapses in the spinal fluid and blood when treatment was stopped. Several cases of the diffuse cerebrospinal group were included. One of the patients with the diffuse cerebrospinal type of disease was markedly improved subjectively while six were slightly benefited. Improvement was noted in the spinal fluid of six, but no significant changes in the Kolmer reaction on the blood were recorded.

MODIFICATIONS OF THE USE OF TRYPARSAMIDE

When we first began the use of tryparsamide it was given in conjunction with mercury salicylate or bichloridol; later, in conjunction with the daily injection of mercury succinimid with or without mercury rubs in the interval; and more recently with potassium bismuth tartrate with butyn, 0.2 gm. every five days or once a week for twenty injections. In reviewing the entire series it appears that the patients who received bismuth showed more improvement than those who were given the various mercurial

preparations, but it will be necessary to carry this observation further before making deductions. The use of tryparsamide in alternation with intraspinal medication every two weeks according to the Swift-Ellis-Ogilvie modification (arsphenamine reinforcement) did not give as good results as tryparsamide alone. Likewise, weekly injections of tryparsamide followed by spinal drainage every two weeks did not improve the clinical or serological results.

The more intensive use of tryparsamide seems to offer more encouraging serological results. A total of seven courses, or seventy injections of tryparsamide, is the most we have given to one patient. In our experience the outstanding clinical improvement has, in the majority of cases, followed the first or the second course rather than the fourth, or subsequent courses. The patients in the group which showed reversal of the spinal fluid reaction to normal received an average of thirty-four injections before the serological reversal was noted, whereas the patients in the group which showed the maximal clinical improvement received an average of slightly less than twenty injections.

CLINICAL AND SEROLOGICAL RELAPSE

The patients who showed clinical or serological improvement were especially studied for evidence of clinical or serological relapse.

In the group of patients with paresis there were two whose fluid reaction reversed to normal following tryparsamide but relapsed when treatment was discontinued. Five others had repeated meningeal relapses, as evidenced by the marked increase in the cell count during the intervals between treatments. In the entire group of 113 patients there were fourteen whose spinal fluid reaction showed a definite improvement or reversal to normal following the administration of tryparsamide, but a relapse during the intervals. The estimate of relapse was based on the increase in the cell count and reversal of the Kolmer reaction. There were three patients with paresis who had a clinical relapse following definite subjective improvement, and also a patient with gastric crises who was definitely relieved for ten months after all other therapeutic measures had failed.

Tryparsamide exerted no greater influence in preventing the clinical or serological relapse than did routine treatment. Those who had shown a tendency to relapse under the usual measures continued to do so under tryparsamide.

COMPLICATIONS

In reviewing the visual complications the entire series (207 cases) was studied. A member of the section on ophthalmology examined all patients who were considered candidates for tryparsamide treatment and those who showed evidence of syphilis of the optic nerve or its constituents were excluded. Twenty-three patients (10.6 per cent.) complained of visual defects while under treatment; the defects in nine of these (4.3 per cent.) were associated with objective findings, while in fourteen (6.8 per cent.) they were subjective complaints and showed no changes in the fields or fundi. The subjective complaints were dazzling lights, blurred vision, and visual hallucinations. In five of the group which showed objective findings the findings were permanent. Three of these had persistently contracted fields and two a homonymous hemianopsia. There were three patients with tabes dorsalis who were found to have early signs of optic atrophy subsequent to several courses of tryparsamide, and two patients with advanced optic atrophy who had only light perception did not lose what vision they had after three courses of tryparsamide. The cause of the visual complication is not as yet understood although we believe that Lillie's conception, that syphilis and not tryparsamide, is frequently the factor, is still tenable.

Our experience does not permit us to ignore subjective complaints, nor do we feel justified in continuing treatment unhesitatingly when such complaints are present. In most cases the subjective complaints are transient, but occasionally if treatment is continued it will result in permanent damage. The cases in which the contracted fields were permanent were all of the tabetic type; in none of the frank cases of paresis were any of the visual complications permanent. This study confirms the observation of Young and Loevenhart that the great majority of the optic complications appeared during the first course of treatment, in our series on an average with the fourth treatment, although there were two cases in which the objective findings appeared after the twenty-first and twenty-fifth injection, respectively. One patient had received a combined course of five injections each of tryparsamide and arsphenamine in alternation. On his return for the second course, tryparsamide alone was given, and following the fourth injection he developed a contraction of the fields which cleared up when he received daily intramuscular injections of mercury succinimid and sodium iodide intravenously.

RESULTS FROM TREATMENT WITH TRYPARSAMIDE IN 113 CASES OF NEUROSYPHILIS OBSERVED FOR THREE YEARS

		Cerebrospinal fluid		*Clinical results*			*Blood Kolmer reaction*	
Symptoms	*Cases*	*Complete reversal of all factors to negative*	*Serological improvement*	*Marked improvement*	*Slight improvement*	*No change*	*Reversed to negative*	*Unchanged negative or positive*
General paresis	50	10	16	6	33	11	8	42
Asymptomatic paresis	15	1	8	1	8	6	4	11
Tabes dorsalis without crises	14	1	6	1	2	11	..	14
Tabes dorsalis with crises	11	1	2	1*	2	8	1	10
Congenital neurosyphilis	6	..	2	..	2	4	..	6
Unclassified	17	..	6	1	6	10	..	17

*Relapse in ten months.

The administration of tryparsamide was followed by various other complications: jaundice, a mild exfoliative dermatitis, and a late nitritoid reaction. Each was noted once. The evidence does not warrant attributing the jaundice solely to the tryparsamide. The attack was mild and did not persist with the continued use of the drug. The dermatitis appeared in a patient with a history of an eczematoid dermatitis of hands and face of many years' standing. He had previously undergone four courses of arsphenamine without a cutaneous reaction. The dermatitis was relatively mild and responded readily to treatment. However, the use of tryparsamide was discontinued. The nitritoid reactions were observed during the sec-

ond course in a patient with paresis. The reactions were partially controlled by employing the Bezredka technic, as recommended by Stokes, for the remainder of the course. Following the second injection of the third course (dose two gm.) the reaction recurred and became increasingly worse with each of the three subsequent injections, so that eventually it was discontinued. The reaction came on from three to five hours after the injection with flushing, tachycardia, nausea, vomiting, dyspnea and backache. It lasted about one hour if untreated, but was controlled readily by the use of epinephrine. Another patient had nausea and vomiting with each injection but this was a psychic phenomenon.

In the treatment of the complications we have administered sodium thiosulphate and alkaline potions. When the patients presented optic complications mercury given intramuscularly and iodids have been beneficial, although, of course, in many cases the subjective visual complications disappear spontaneously.

CONCLUSIONS

The use of tryparsamide at the Mayo Clinic extending over a period of three years, in 207 cases, leads us to believe that although its use is still in the experimental phase, tryparsamide is of value in the treatment of the paretic type of parenchymatous neurosyphilis. It does not seem to offer as much encouragement as the treatment of general paresis with malaria but it is available for those not suited to the risk of the latter treatment. Our evidence, based on subjective and serological improvement, justifies the assertion that there is a certain small group of patients with early paresis who derive marked benefit from tryparsamide. In seven cases in the whole series there was a complete reversal of the spinal fluid findings to normal but no associated clinical improvement. We were unable to ascertain the clinical and serological criteria by which to determine beforehand the patients with paresis who will improve. The objective visual complications offer a hazard (4.3 per cent.) which could not be prevented by special precautions. The mechanism of this complication has not as yet been described. The use of bismuth intramuscularly in conjunction with tryparsamide seems to offer better therapeutic results than either given alone. The low cost, availability, and small percentage of complications and reactions are among the advantages of the drug. The continued clinical use of tryparsamide may eventually determine the niche in the armamentarium of neurosyphilitic treatment in which it is to fit with the most encouraging results, but until that time its use is warranted as a valuable adjunct in the treatment of the patient early in the course of general paresis.

General Pathology of Syphilis in the Primary Phase

J. GOLAY, M.D.
Geneva, Switzerland

The older physicians did not attribute the same importance to the primary phase of syphilis as we do today. The classical writers merely looked upon the chancre as the point of entrance preceding the symptoms of constitutional infection. The diagnosis of the primary sore was often left in suspense until the presence of the secondary manifestations and treatment was not begun before the development of the roseola. This practice had its *raison d'être* in the doubt which so often existed in respect of the diagnosis of an infecting chancre, a doubt which was not cleared up until several weeks had elapsed, in other words, after the purely local infection had become generalized.

Some observers even went further and advised abstaining from treatment in cases where there was no doubt whatsoever as to the specific nature of the primary lesion. It was maintained that immediate treatment might have as a consequence to impede the normal resistance of the organism in respect of the syphilitic injection and, consequently, would favor its ultimate development and generalization of the morbid process. It is clear that the mercurial treatment used was in most cases quite incapable of preventing the outburst of general accidents and the most to be expected of it was to delay somewhat their appearance. Hence it came to be readily understood that the primary phase did not offer any particular interest.

Today our conceptions have decidedly changed and there is now no syphilologist who does not consider that it is during the first few weeks of the disease that the chief acts of the drama are played, whose multiple consequences will later ensue. It is during this phase that the spirocheta, after local proliferation, invades the entire system; it is during this phase that in a large measure depend the various specific localizations which will become apparent during the

evolution of the disease; it is during this phase only that treatment may, if properly carried out, definitely control the affection. One can therefore affirm that the primary phase of lues is the most important phase of its evolution. For this reason it is absolutely necessary to understand precisely the phenomena succeeding each other during the first and second periods of incubation and to know the different dates at which these phenomena occur.

PROGRESSION AND DISTRIBUTION OF THE SPIROCHETA

1. *First incubation.*—This includes the time elapsing between the inoculation of the treponema in the tissues and the appearance of the clinical symptoms characterizing the chancre. This period has an average duration of from twenty-five to twenty-eight days. The length of incubation of syphilis is due to the fact that the treponema encounters some difficulty in becoming acclimated to its new conditions of life and nutrition, and it does not succeed in multiplying until it comes in contact with living cells, especially the endothelium lining the lymphatic vessels (Lévy Bing and Laffont). So soon as they have penetrated a new organism, the spirochetæ divide up into several distinct groups.

Some remain on the spot of inoculation. These are those who by their proliferation will give rise to the primary accidents. The existence of this group of spirocheta has been sufficiently demonstrated by the appearance of the chancre at the point of inoculation. The classic writers already taught the first lesion of lues always arose at the point where the virus had penetrated; the discovery of the treponema and experimental work have furnished the incontestable proof of this affirmation. Hence it is an acquired fact that proliferation of the spirocheta takes place on the spot.

From the onset of the first incubation a certain number of spirochetæ directly penetrate into the general circulation. The existence of this group of treponema is no longer a matter of doubt and is based upon the experiments carried out by Neisser. He has, in fact, shown that quite a time before clinical appearance of the local manifestations in inoculated monkeys, a number of spirochetæ take the blood route to reach, and become fixed in, the various viscera, especially the lymph nodes, spleen, bone marrow, and testicle. Therefore early invasion of the circulation is not only possible, but certain.

Lastly, the third group of parasites travel up the lymphatic tract. This penetration of the infecting organism into the lymphatic system takes place slowly and progressively, but surely, starting from the point of inoculation and attaining the first regional lymph node. This is so true that the satellite adenopathy of the chancre has always been regarded as of as much or even more diagnostic value than the clinical aspect of the primary sore itself. We know that the enlarged lymph node can be detected almost immediately after the appearance of the chancre; therefore it is clear that the local lymphatic tract is invated already in the first incubation.

2. *The syphilitic chancre.*—While the phenomena mentioned are taking place, the primary sore begins to appear at the point of inoculation. I have no intention to describe a syphilitic chancre, and would only draw attention to a few of its characters. It is, in reality, a superficial wound, or erosion, has a smooth fundus, ham red in color, regularly round or oval in outline, and reposes upon an indurated base. Curiously enough, histologists have shown that the induration of the chancre is not invariably in proportion to the lymphocytic infiltration and it may well be asked whether or not it is partially due to a phenomenon vastly different from leucocytic reaction arising against ordinary infections. There is a striking fact, namely, that by successive subcutaneous injections of serum into animals one can, as Arthurs has shown, at length produce an indurated infiltration at which point a thick, whitish, aseptic exudate will soon appear and will end by the elimination of a patch of gangrene. It is not at all impossible that the induration of the primary sore, if not its other characters, may be dependent upon a similar reaction resulting from the incessant arrival at the same spot of toxins derived from the spirocheta.

The syphilitic chancre is not always the same in each case. Sometimes it is seen as a minute erosion reposing on no induration whatsoever, or only to a trifling one. On the other hand it may appear in the form of a mummulary wound surmounting a nodular induration or it mav assume the aspect of a deep ulcerating process. These differences may be due to microbic associations, but generally they are dependent upon the local reactions of the subject or to allergic phenomena. We now know that allergy is not absolutely specific, therefore it is not at all astonishing that it may manifest itself at the time of the first accident produced by syphilitic infection.

According to some observers syphilis may exist without the development of a chancre. This opinion requires careful examination. It is true that one frequently meets with patients presenting more or less late specific lesions who have no recollection of having previously been infected. These are instances of so-called unknown syphilis and they are legion. But it does not follow that a chancre has not previously existed, and with Fournier we may admit that the initial sore has simply passed unnoticed. This supposition appears to be all the more acceptable because the majority of these cases occur in women.

However, some observers have recorded cases of syphilis without a chancre, which, at first sight, seem to leave little room for doubt. These are instances of young men who after a suspicious coitus have been carefully followed by their physician from the time of the suspected contamination to the development of the primary accident. It is true that such cases are not numerous since Gerbay in a recent study, has only been able to collect fifteen that appear to him to be authentic; on the other hand, it is clear that even in the male an absolutely complete examination is a difficult matter and certain rectal or urethral chancres must of necessity pass unnoticed by even the most competent practitioner. It is not even certain that the primary accident may not occasionally develop in certain mucosæ of the internal organs, such as the stomach, as Nicolan appears to admit.

Another striking thing is that in all these cases, the observers have noted the presence of the stellite adenopathy. This fact alone is enough to make the nonexistence of the syphilitic chancre doubtful. But this is not all, because in these various instances the

adenopathy has developed exactly as when a chancre has been detected, while the secondary accidents have appeared within the normal lapse of time. Consequently, in all these cases, the chancre has unquestionably existed although it escaped detection.

Why these conclusions? Because the evolution of syphilis without a chancre—some undoubted examples of which are to be found in the literature—is quite different. Usually they are cases of physicians who have pricked themselves during a surgical operation and later presented secondary lesions although no initial sore developed at the site of inoculation. All these cases, excepting the one recorded by Walloch, are different from the others because there was absence of the satellite adenopathy and the early appearance of the roseola not later than the thirty-third day following the inoculation (Julien's case); otherwise five to six weeks sooner than in ordinary cases. This evolution is clearly that of syphilis at the first onset, because it corresponds with what we know of experimental lues by injections of the spirocheta directly into the general circulation in animals.

Therefore it has been experimentally shown and in certain very exceptional clinical circumstances realized by deep inoculation of the treponema into the blood vessels, that syphilis may develop without a chancre. It is, however, nevertheless true that in practice, acquired symphilis always begins with a primary accident and that today we still can confirm Fournier's statement that cases without a chancre are almost always "incompletely . . . observed cases whose exordium has been overlooked and whose initial history has remained unrecognized for some reason or other."

3. *The second incubation.*—From the onset of the chancre, the disease enters upon a new phase of its evolution, viz: the second incubation. This period whose total duration is about six weeks, ends with the appearance of the secondary accidents. We have pointed out that at the end of the first incubation, the spirochetæ are divided into three groups; it is now time to follow their ulterior career.

The treponema which have remained at the point of inoculation and have given rise to the chancre more or less completely disappear. Destroyed by local organic reactions, they play no part in the generalization of the syphilitic process. The proof of this disappearance is furnished by normal and usually definitive cicatrization of the sore. During the second, as during the first incubation, a few spirochetae pass directly into the general circulation (Frühwald). This is the result of the persistence of blood emboli.

During this phase there is a progressive invasion of the lymphatic system, the onset of which, as we have shown, is during the first incubation. Consequently two routes appear to be freely open to generalization: the general circulation and the lyphatic system. Which of these is the most important? This question must now occupy our attention. My personal conviction is that invasion of the organism essentially takes place by the intermediary of the lymphatic system. This opinion is the outcome of a paper written with the collaboration of Dr. Weyl. (1) We would here develop our point of view and later will discuss the arguments put forward in favor of generalization by way of the circulation.

Although early invasion by way of the circulation has been absolutely demonstrated, it does not necessarily follow that this septicemia offers great practical importance. On the contrary, it would seem that here we are dealing with minute emboli, composed of a few parasites whose life is ephemeral. These emboli are perhaps responsible for certain visceral lesions of rather late development, but they certainly do not play any part in the eclosion of the secondary manifestations. Later on we shall furnish many proofs sustaining this view; it is, however, interesting to remark that the roseola is absent from the symptomatology of hereditary syphilis, which as is well known, is from the onset, a blood syphilis.

The penetration of the lymphatic system by the infection plays, on the contrary, an important part in the generalization of the disease. It is upon it, and it alone, that the subsequent evolution of the affection appears to depend, and it is the only occurrence upon which depends the development of the roseola. This route of extension of the infection has not need of any lengthy demonstration.

The appearance of successively infected lymph nodes, as is clearly made evident by the cervical lymphatic chain in cases of chancre on the face, furnishes the clinical proof (Sabaréanu). On the other hand, the well known plate published by Fournier concerning the abdominal lymphatics of a subject who died accidentally during the second incubation of a genital syphilis, gives us the anatomical demonstration.

After having progressively broken through several clusters of lymph nodes, the spirocheta attains the thoracic duct and then the subclavian veins and from this time on, the secondary phase is theoretically constituted. This "major septicemia can in no way be compared wtih the tiny swarms of spirochetæ entering the blood stream during the first incubation. In the circumstance under consideration we are witnessing a pouring *en masse* of the treponema into the blood stream. This violent entry into the blood in all probability takes place with great rapidity, since the eclosion of the secondary accidents as a rule ensues at once and from the start the lesions are generalized.

This conception is corroborated by the fact that the time of the appearance of the roseola is considered advanced when the primary accident arises on the face instead of the genitalia (Gaucher and Milian, Luisi). In these circumstances how can one explain the very early development of secondary accidents if not by the fact that the distance covered by the treponema from its point of inoculation to the general circulation is very much shorter and that the number of clusters of lymph nodes capable of hindering its onward progress are fewer. Hence the appearance of secondary symptoms is governed by this pouring of the spirocheta *en masse* into the great lymphatic tract and then into the subclavian veins. It is only after having progressively travelled through the entire extent of the lymphatic system that the treponema penetrates into the general circulation.

It is of the highest practical importance to know at what time this penetration into the circulation occurs; otherwise put,—what date in the primary evolution corresponds the generalization of the disease. Now it is possible to affirm that it takes place from

ten to fifteen days before the appearance of the roseola. This affirmation rests upon the following four data:

1. If at the onset of the second incubation the subject be inoculated with the serum taken from his chancre the result will usually be positive if the point of inoculation be somewhat distant from the primary accident (Wallace, Auspitz, Poutoppidan, Queyrat). Now, the lesion provoked by reinoculation, should it become apparent within the ten last days of the second incubation, is not the same as when it is already positive before this date. Sabaréanu has in point of fact shown that when the inoculated accident manifests itself sufficiently soon, that is to say, more than ten days before the roseola, it assumes the aspect of a chancre, while in contrary circumstances only a pupule appears; otherwise put, an aborted chancre or a lesion of secondary type. This difference can only depend upon the question of cutaneous immunity. Absent during the first few weeks of the primary phase, this immunity begins to show itself ten days before the secondary eclosion. Its onset certainly coincides with the generalization of the infection (Hudelo) and this generalization therefore precedes the roseola by ten days.

2. We know that the early secondary accidents produced by an irritation are met with only during the ten to fifteen days preceding the appearance of the roseola. The fact is that before this date the spirocheta has not reached the skin and also previous to this date the septicemia has not developed.

3. Yet another proof of what I maintain is furnished by the fact that a pregnant female who contracts syphilis during her gestation generally gives birth to a healthy child if she has contracted lues during the two last months of pregnancy (Ricord, Diday, Priem, Sabaréanu). Consequently it is only after the sixtieth day following contamination that a mother can syphilize her offspring, otherwise put, the spirochetal septicemia is only constituted from this date on. If we take twenty-five days as the average time of the first incubation, and forty-five days for the second, we obtain a total of seventy days; otherwise, ten days earlier.

4. Finally, experimental data agree with clinical findings. Finger and Landsteiner have shown that the duration of incubation of experimental inoculation in the monkey during the second incubation is from ten to fourteen days. Whether the spirocheta is derived from the blood or from an experimental inoculation, this lapse of time must remain the same. The spirocheta consequently reaches the skin ten to fourteen days before the eclosion of the secondary accidents. For all these reasons it is clear that the septicemia precedes the roseola from ten to fifteen days.

To sum up, it may be said: if from the first incubation the spirochetæ become divided into three groups, the local, the blood, and the lymphatic groups, only one of them retains importance for the outcome, namely, that one which progressively invades the lymphatics. This extension is of long duration because the treponema must successively break through a rather large number of lymph nodes which offer just so many barriers. It is only from ten to fifteen days before the development of secondary symptoms that the infection reaches the general circulation and it is from this time that generalization of the process dates.

Such is my personal conception of the process but it is not the one accepted by the majority of modern syphilologists. Since the time when Neisser demonstrated that the blood and certain viscera may be cirulent a few days after inoculation, the number of partisans of generalization by the circulation has continued to increase. It is far from my thought to deny the existence of these septicemias arising at the very onset, as these have been clearly demonstrated to exist and are above any discussion. It is certain that during the first incubation a few spirochetæ have entered the tissues, especially the lymph nodes, spleen, testicle, and bone marrow. But it does not necessarily follow that this generalization via the circulation offers practical importance. On the contrary it is probable that the few spirochetæ drawn directly into the general circulation are for the most part rapidly destroyed, because we know of no specific lesion which is unquestionably dependent upon these early septicemias. The treponema can at most be held responsible for a few later visceral lesions; it certainly plays no part in the production of the secondary eclosion.

Gerbay, who has recently published a very interesting paper entitled, The Bordet-Wassermann Reaction and the General Pathology of Syphilis During the Primary Period is a warm partisan of generalization via the blood. This observer, whose opinion reflects that of many modern syphilologists, bases his arguments essentially on the writings of Neisser, to which I have referred, and upon the fact that "the first lesions produced by the treponema at the spot of inoculation, are lesions of the blood vessels." He relies principally on Darier's histological description of the chancre: "The treponema especially multiply in the walls of the blood vessels and from them appear to migrate into the vascular lumen, which, from the viewpoint of generalization of the infection, is highly important; others invade the connective tissue fasciculi and space from whence the lymphatics transport them to the lymph nodes."

From this description it is evident that the spirocheta is lodged especially in the vascular walls, but it is also said that they appear in part to emigrate into the lumen of the vessels, in part into the lymphatics. Levaditi and Manouélian have demonstrated their presence in the lumen of the superficial capillaries of the dermic papilæ and in the albuminous contents of the dilated lymphatic spaces. Lévy-Bing and Laffont recall that the blood of syphilitics is contagious and they add: "From microscopical studies of human or experimental chancres it has been shown that the treponema is also met with in the lymphatic dilatations present in the neighborhood of the chancre. Therefore from these findings it is logical to admit that the treponema selects the circulation for its dissemination throughout the organism and preferably, perhaps, the lymphatic route." And further on they say: "The spirocheta is only successful in multiplying when in contact with living cells and among these it seems to prefer the epithelia, as well as the endothelium lining the lymphatic vessels."

Histology therefore does not demonstrate that the treponema of the chancre preferably invades the general circulation. On the other hand, clinical studies

distinctly prove that it is in the lymphatic spaces that the gross masses of the parasite are to be found. In point of fact, it is easy to demonstrate microscopically the presence of the spirocheta in the primary accident if one is careful to obtain serum from the lymphatic spaces and in so doing not to cause bleeding. To conclude, it may be said that both routes, the blood and the lymphatics, appear to be equally open to the generalization of the infection. The essential is to ascertain which of the two is the most important.

To do this we must leave aside this statistical study in order to approach the dynamic study of data which characterize the primary evolution. Now here no doubt exists; the principal generalization takes place by the lymphatics. Why? Because the hypothesis of blood generalization explains nothing. In particular it does not explain why the roseola only appears about seventy days after contamination, instead of appearing at the latest on the thirty-third day as in cases of direct blood inoculation. Neither does it explain why the secondary accidents occur earlier when the primary accident occurs on some part of the head instead of on the genitalia. On the contrary, lymphatic generalization explains everything. The very late appearance of the secondary phenomena is due to the long distance that the spirocheta must cover in the lymphatic system before being poured into general circulation. The early appearance of roseola in cases of chancre on the head or face results from the fact that the parasite has a much shorter distance to cover from the point of inoculation to the general circulation and the number of clusters of lymph nodes, which hinder its progress, are much fewer. Lymphatic generalization also explains why a female, syphilized during the last two months of gestation, usually gives birth to a healthy offspring, and that general immunity, as we shall attempt to show, is hardly ever constituted before ten days preceding the eclosion of the roseola.

The partisans of generalization via the blood stream are of the opinion that the roseola only appears seventy days following contamination, because the lesions of the integument become apparent only when the cutaneous allergy is sufficiently developed. Given the fact that certain cases of syphilis rapidly become allergy (early malignant syphilis) and that others are never allergy (tabes dorsalis, general paresis), the development of the roseola should be, as is the case of tertiarism, variable as to time, which is not the case. On the other hand, it would have to be admitted that allergy is always earlier when the chancre is cephalic and that it is still more rapidly constituted in cases of direct blood inoculation, which is an impossibility.

Dr. Gerbay maintains that my conception "does not appear exactly to correspond with what we know of the normal and pathological lymphatic circulation." In his opinion we must make two distinctions; firstly, the lesions of the lymphatic system, and secondly, the transportation of the treponema by the lymphatics up to the general circulation." He goes on to say: "This adenopathy and lymphangitis progresses slowly and the anatomical changes likewise. But how can it be admitted that the treponema contained within the lumen of the lymphatics cannot be carried by the circulating lymph beyond the diseased portions into unaltered vessels?"

Things would clearly take place in this way if, along the course of the lymphatics, there were no lymph nodes whose principal function is to oppose rapid generalization of the infection. In all reasonable probability the spirocheta cannot break through them until it has multiplied for some time. Each lymph node represents a relay from which the treponema cannot escape until it has remained for a certain length of time. When once the last relay has been passed the parasite is poured *en masse* into the thoracic duct and this phase corresponds to what I have called the major septicemia.

Lastly, there is an argument that I have frequently encountered in favor of generalization via the circulation, namely, the uselessness of excision of the syphilitic chancre. I am unable to see why this fact, although in itself perfectly true, should demonstrate that organic invasion selects one route rather than another, since it is proved that at the time of the appearance of the primary accident, the spirocheta has already reached the regional lymph nodes.

CONCLUSION

The generalization of syphilis essentially takes place by way of the lymphatics.

Immunity. For years the profession supposed that syphilis was not reinoculable because one infection conferred immunity in every way similar to that occurring in most infectious diseases. At the present time we know that all this is exploded and that a subject cured of his syphilis is immediately susceptible of contracting a new infection. "The refractory state of those formerly syphilized merely consists of a persistent state of syphilitic infection and not a state of immunity." (Nicolas.) We even know that there is hardly any phase in the syphilitic evolution in which immunity of the skin is absolute in respect of spirochetic inoculation, although in the vast majority of cases the production of a new chancre does not ensue, but in its stead an accident offering the symptomatology of the phase considered appears. Hence there is no true immunity to syphilis, taken in the sense of microbic infections in general. Yet syphilitic immunity is not a vain word; thoroughly to understand it, it is enough to recall that lues, being due to a flagellated organism belonging to the family of trypanosomides, the real immunity it confers is to be compared with that of other spirilloses. Levaditi has shown that animals suffering from trypanosomiasis (nagana or surra) are refractory to a new inoculation. The trypanosoma which is destroyed *in vitro* by the animal's serum has, on the contrary, acquired a more or less absolute insensibility in respect of the trypanosomolytic antibodies, because the blood of those animals contains trypanosome. If these data be applied to syphilis it may be assumed that a subject may harbor the spirocheta for forty or fifty years while his skin and mucosæ will not react to a new inoculation. But so soon as he is freed from his blood infection, whether a complete cure has been obtained or his affection has become distinctly localized, he is susceptible of being again newly infected. (Fordyce.)

From all this it is clear that syphilitc immunity is essentially represented by a special state of the integuments and mucosæ rendering them more or less refactory to a new inoculation.

With Burnum, Gaucher, and others, I am convinced that syphilitic immunity is local before becoming general. It only is manifest at the onset in the area immediately around the chancre. This conception is derived from the following two data:

1. Reinoculation of the primary accident at a point near the primary erosion generally gives a negative result, while it is frequently positive when the inoculation is undertaken sufficiently early in a region distant from the chancre.

2. The Bordet-Wassermann reaction made with the serum from the chancre give a positive result from the very onset of its development, while a positive reaction from the blood only takes place much later.

In my opinion this second test has a very small demonstrative value, inasmuch as it is not at all certain that Wassermann's reaction is governed by a specific antibody, as is theoretically supposed. On the contrary, it would certainly seem that the seroreaction is directly provoked by the spirocheta and its toxins, hence it is not related to the organic defence of the subject. For that matter, this in no way infirms my point of view which is sufficiently demonstrated by reinoculation experiments and clinical data, namely, that immunity is local long before it becomes general.

This theory of regional immunity is, however, not admitted by everybody; it is for Gerbay, a very moot point and in respect of this he refers to Marcel Pinard's opinion, namely, if immunity "becomes established slowly, it seems to require the same time for regions remote from the chancre. Autoinoculations show this clearly. Possibly, in general, during the first eleven days only, they develop in an absolutely similar fashion when done on the abdomen or arm, in the case of a genital chancre." The latter affirmation simply confirms my point of view, which is that of Gaucher, namely, that the syphilitic virus follows the course of the lymphatics and thus immunizes the territory that it traverses. Nnw, the spirocheta, in the case of a genital chancre, certainly does not pass through the superficial abdominal lymphatics, therefore there is no reason why the abdomen should be more refractory than the arm to an autoinoculation done at the onset of the second incubation. On the contrary, this inoculation is invariably negative if it is done along the course of the local lymphatics.

Local immunity is consequently early in its development. As to genearl immunity, it develops later, but at what time?

Queyrat has shown that, as a rule, the chancre can only be inoculated during the first ten days of its existence, and it has been concluded that immunity is constituted from this date on. Now nothing seems to me more questionable. The date of the inoculation possesses no importance whatsoever. What should be known is just up to what time a previous inoculation still manifests itself by a lesion presenting the characters of a syphilitic chancre. Otherwise put, the incubation of the inoculation accident must be fully taken into account.

Two examples may, perhaps, better illustrate my thought. Let us admit that general immunity begins the thirty-fifth day of the chancre.

First example. On the eighth day an inoculation is made whose time of incubation is twenty-five days. This inoculation will become apparent on the thirty-third day, because at the time a general immunity is still absent.

Second example: On the fifteenth day an inoculation is made whose time of incubation is twenty-five days. This inoculation should be manifest on the fortieth day, but it remains negative because immunity has taken place five days previously.

Now, Sabaréanu has shown that when the inoculated accident manifests itself rather early, otherwise more than ten days before the roseola, it assumes the aspect of a chancre, and that on the contrary, if it develops later all that will develop is a papule—an aborted chancre or an accident or secondary kind. This difference can only be due to the presence or absence of general immunity.

Therefore I conclude from these facts that general immunity is hardly developed until ten days before the appearance of the secondary accidents. Although local immunity occurs very early, general immunity is, on the contrary, late in development.

The study of the pathology of primary syphilis not only presents a great scientific interest, but it can also lead to practical conclusions of the highest importance.

It is known that the seroreaction becomes positive from fifteen to twenty days after the appearance of the chancre, therefore from fifteen to twenty days before the advent of the septicemia and general phenomena of immunity. Hence it is impossible that it is dependent upon general organic immunization. It appears to be governed by the penetration into the blood stream of the toxins derived from the parasites still confined in the lymphatics, penetration which clearly is in advance of the septicemia itself. Wassermann's reaction is not governed by a phenomenon of immunity; its positivity depends simply on the presence of a sufficient quantity of the spirocheta toxins in the general circulation.

The study of other phases of syphilis only confirm this point of view. From these data a primordial fact is derived from the therapeutic standpoint, namely that the appearance of Wassermann's reaction does not constitute an important date in the primary evolution from the viewpoint of aborting syphilis, because it corresponds neither to the septicemia nor to general immunization.

I am perfectly well aware that this conclusion is in flagrant contradiction with the present day teachings in respect of abortive treatment. I do not underestimate the great difficulties to be met with in attacking an almost intangible dogma, which may be expressed as follows. Abortion of syphilis is easily realized so long as the seroreaction is negative; once this phase passed, it is both difficult and uncertain. In point of fact, the date of the appearance of the serologic positivity plays in the minds of most physicians, a very important part and so to speak, constitutes a kind of distinct barrier separating two distinct phases beyond which, the disease having become generalized is much less easily curable. I do not deny that sterilization of a syphilitic is all the more difficult the longer the lapse of time since the onset of the chancre, but I pretend that we are dealing with a regular progression corresponding with the progression of the parasites in the lymphatics and that there is no sudden jump at the time serological posi-

tivity arises. The numerous statistics destined to demonstrate the contrary, all of which are established after the same pattern, namely, with *a priori* idea of the importance of a positive Wassermann, simply prove that abortion of the disease is all the easier, the earlier it is attempted. This line of demarcation separating the prehumoral and serological phases is absolutely fictitious and corresponds to no major pathological phenomenon, hence it possesses only a relative value in practice and above all from the therapeutic standpoint. This is what we have attempted to show (2) basing our work on Prof. Oltramare's clinical material, and we have looked for this demonstration in the fact that no matter what way the second incubation may artificially be divided, that the line of demarcation be placed at the tenth, twentieth, or thirtieth days of the chancre; the first always shows a higher percentage of cures than the second. To make this demonstration more certain still, I have divided my cases into four successive categories, as follows:

1. Patients treated during the first ten days of the second incubation,—twenty-five, with four relapses, sixteen per cent. failures.
2. Patients treated beginning the tenth to the twentieth day,—fifty, with seventeen relapses, thirty-four per cent. failures.
3. Patients treated beginning the twentieth to the thirtieth day,—twenty-two, with ten relapses, fory-five and five tenths per cent. failures.
4. Patients treated beginning the thirtieth to the thirty-fifth day, ten,—with six relapses, sixty per cent. failures.

The percentage of failures, that is to say, of abortive treatment, clearly progresses the more remote is the date of the chancre, and this progression is so regular that were the figures put on a chart, they would give a straight ascending line.

Consequently, the appearance of a positive Wassermann does not represent an important phase in the primary evolution from the viewpoint of therapeutics.

CONCLUSIONS

From the first and during the entire second incubation, some spirochetæ enter the general circulation, but so few in number that it has no practical importance.

The true septicemia occurs ten to fifteen days before the onset of the secondary phenomena; it is governed by the pouring into the subclavian vein of a great mass of parasites coming from the thoracic duct. It is only after having traveled through the entire lymphatic system that the spirocheta reaches the general circulation. If local immunity occurs early, general immunity, on the contrary, is late; it hardly becomes apparent before ten days previous to the roseola.

The appearance of seriological positivity does not represent an important phase in the primary evolution either from the viewpoints of pathology or therapeutics; in point of fact it does not correspond with either the socalled major septicemia or general organic immunity.

Dactylitis Syphilitica

DOUGLASS W. MONTGOMERY, M.D.
and GEORGE D. CULVER, M.D.
San Francisco

The clinical picture of dactylitis syphilitica, or spina ventosa luetica, is quite striking, and therefore is often represented in textbooks. It is a spindle shaped swelling with, usually, the thickest part of the spindle in the middle of the length of the finger or the toe. Characteristic as it may be, however, the following case illustrates some of the difficulties which may surround the making of a definite diagnosis.

Case.—On June 4, 1925, a woman forty years of age came into the office with the right third toe swollen to this peculiar shape. The history, however, did not quite accord with the first impression. She said that she had been using a corn medicine over the first phalangeal joint, and that on cutting the corn she made a wound. After this the member became red and swollen. On closer examination a sinus was seen leading straight down to the joint, and up through it there oozed a glairy pus. This joint and the first phalanx, as well as the soft parts, seemed all to be swollen. The skin was deeply reddened, and the question naturally arose, had possibly an infective process, beginning in the wounded corn, spread deeply into the joint and along the periosteum? Streptodermias, which are so superficial and fleeting about the face and head, are often both tenacious and deeply penetrating on the feet and legs, in which the circulation is more sluggish. And it was here noted that she had dusky feet, although the pulse in both post tibials was distinct.

As for her social history she had been married in 1909 to a man of dissolute habits, from whom she was now divorced, and who seems to have suffered, at any rate, from gonorrhea. She never became pregnant.

There was another feature of the case which also did not seem to accord with our first impression which, it will be recalled, was that we were dealing with a luetic affection. From early girlhood the right foot had been sensitive to injuries. For instance, as a child she remembered that in breaking in new shoes the right foot was likely to suffer pain. At

dances, too, it would pain severely if accidentally struck, and her husband used to remark that it was strange that she should complain when nothing could be seen. In 1918, when thirty-three years of age, the fifth right toe swelled and became reddened, and burst and discharged pus. One day in August, 1919, her medical attendant found that it contained no bone, and he clipped off the dangling piece of flesh.

Fig. 1.—The noteworthy points are—the loss of the fifth toe, the deformity of the fourth and the spindle shaped swelling surmounted by a corn of the third. With a lens the slitlike opening can be seen in the centre of the corn.

In the following spring the right fourth toe underwent the same kind of inflammatory process, and this time the bone was scraped, and she received injections into the blood. Prompt healing took place, which was yet firm with retention of the bones of the toe, although, as will be seen later, the first phalanx was permanently affected. We could not ascertain if at that time her treatment had been antiluetic. In fact, she did not give us the slightest hint that she suspected her trouble to be luetic. The long years of sensitiveness of the foot and the slow, and seemingly inevitable, sequence of the affection of the toes from without inwards gave rise to the suspicion of a progressive trophic neural trouble. The skiagraph also showed atrophy of the distal end of the fifth metatarsal, and of the middle and proximal phalanges of the fourth toe just such as might take place in leprosy, syringomyelia or tabes, or in an injury to the vertebral column pressing on the nerves. There was no dissociation of sensations, however, and the knee jerks were present on both sides. Nor were there any other symptoms present, which could be ascribed to the nerves or to leprosy..

There was still another interesting feature. On examining the skiagraph with a pocket lens three small caritic lesions were found in the midst of the dactylitis. Two of these were of the distal extremity of the first phalanx, and one of the proximal extremity of the second phalanx of the third toe. These showed the disease to be focal and not merely atrophic, and therefore corresponded with the diagnosis of a focal as contrasted with an atrophic disease. This was, strictly speaking, the only direct evidence that the skiagraph presented, but it was definite.

The patient's Wassermann was negative. A therapeutic test was determined upon, and she was put on a mixture containing bichloride of mercury and iodide of potash, and she was directed to rub mercurial ointment into the foot. The improvement noted at her next visit was that usually seen in syphilis, and now as usual we inquired about her gums. She said that her gums were all right, but incidentally remarked that a trouble in the roof of her mouth had also improved. On looking at this what was our astonishment to see a typical gummatous ulcer in the median line at the junction of the hard and soft palate. It was oval, punched out, with a bright yellow floor, and was situated in a scarlet field. As further evidence there was a circular depressed scar to the right of this, but the patient had no recollection at all of the ulcer which had caused it. There was also marked thickening of the mucous membrane on the left side of the septum nasi, with a large ulcer, and perforation. The presence of the lesions in the mouth and naris coincident with the dactylitis showing three widely separated active lesions richly bathed in blood, and the absence of a positive Wassermann reaction was most interesting. One would naturally think that three such active lesions, so widely separated, would inevitably cause an easily detectable seral change.

The patient at first did not complain of any trouble in either the mouth or nose, and it was only on the second or third visit that we examined the mouth, and then as a matter of routine the nose. It is a well known clinical fact that the lesions in the nose are painless, and are regarded by the patient as symptoms of a common cold until suddenly one fine day blood and pieces of bone are blown out into the handkerchief. It is indeed fortunate then if the bridge of the nose does not sink, giving rise to a conspicuous and characteristic deformity.

In the first examination of a patient we almost never fail to look in the mouth, and no doubt it was a technical error not to have done so in this case. If, however, we had found this absolutely conclusive symptom in the first instance, we might have neglected making either a blood test or a skiagraph, and the case would have lost two of its most interesting

Fig. 2.—The atrophy of the distal end of the fifth metatarsal bone, and the thinning of the shaft of the first phalanx, and the distortion of the second and third phalanges of the fourth toe are evident. Unfortunately the caritic erosions, distinct in the skiagraph, show only dimly in the cut.
Radiograph by Ruggles and Bryan, San Francisco.

features, for both the negative Wassermann and the skiograph, which showed on gross examination only atrophy of the bones, might easily have lead to an erroneous diagnosis. It will be remembered that the definite luetic symptoms in this situation were only discernible with a lens.

Still another point in the history was cleared up on ascertaining the true nature of the disease.

It will be remembered that the patient ascribed the inflammation of the toe to infection acquired from cutting a corn. The corn undoubtedly was present, but the reason for it especially troubling her was likely the swelling of the toe from the lues, which also made the corn more easily vulnerable, by bulging up the vascular tissues. The swelling of the toe, therefore, in all probability antedated the supposed opportunity for infection.

There was very little tenderness of the toe, and it could be handled with impunity, nor was there any history of characteristic osteocopic pains. She had a sensation of heaviness in the whole foot, and at intervals she would have sharp lancinating pains shooting up the entire limb, so severe as to awaken her out of a deep sleep, which might readily have been mistaken for the fulgurating pains of tabes.

The discharge from the sinus ceased almost coincidentally with the termination of a ten weeks' course of arsphenamine and grey oil.

Dactylitis syphilitica is a rare affection, and curiously enough, much rarer on the toes than on the fingers. Lacapère, who has had a large experience in syphilis of the bones in Morocco, where the natives are especially prone to this form of the disease, only reports one case, and that one of the great toe. It appears that in Morocco, in late syphilis, lesions of the bones come in frequency immediately after lesions of the skin and mucous membranes, so that Lacapère found in 2,072 patients 495 instances of bone syphilis, and, as before mentioned, there was only one case in which the bones of the toe were affected, whereas the phalanges of the fingers were affected in sixteen instances (1). It must be rare indeed to find a number of toes affected as in this case, for it must be assumed that the previous trouble in the fourth and fifth toes was also syphilitic. We can only ascribe this susceptibility to spirochetal attack to some tissue weakness, of which possibly the tenderness of the foot to traumatism throughout the patient's life may also have been an expression.

The patient, however, seems to have had susceptibility of the general osseous system, for besides the affection of the toes she had a perforation of the septum nasi and the lesion in the palate would undoubtedly have gone on to osteitis of the palate bone if it had not been checked by treatment.

Syphilis of the phalanges usually seems to begin in the cartilage of the joint or in the periosteum, as it appeared to do in this case, and then to spread to the bone, where in this case it had already caused superficial caritic erosions. It would appear that it is only when the Haversian canals are deeply affected that characteristic osteocopic pains supervene.

Neurosyphilis, Its Diagnosis and Treatment by the General Practitioner*

HORACE V. PIKE, M.D.
Danville, Pa.

While in a general way acquired syphilitic infection is primarily a matter of individual and community responsibility, neurosyphilis is to a great extent a purely medical problem, the solution of which lies for the most part not in the hands of the syphilogist or neuropsychiatrist, but rather in the hands of the physician practicing general medicine.

There is no question but that acquired syphilis affects the central nervous system by specific lesions in a considerable proportion of all luetic cases and this is not surprising when we consider that like the skin, which has been regarded as the favorite field of invasion, the nervous system is of ectodermal origin, and in fact the frequent symptoms of nerve root involvement in early syphilis and their relation to the usual location of primary and secondary lesions have been considered by some investigators as suggestive that the cerebrospinal involvement may be by a lymphogenous route from the skin along the sheaths of the spinal nerves. For many years it was generally understood that but one to two per cent. of syphilitic patients became cases of neurosyphilis, but careful and systematic observations over the past ten years would seem to show in at least twenty-five per cent. of all patients there develop cerebrospinal lesions; that one half of all patients during the secondary period show some involvement of the optic and auditory nerves which may be transitory or permanent; and that from seventy to eighty-two per cent. of patients with early syphilitic lesions show spinal fluid changes, while state hospital records show that one out of every six patients admitted as insane owe their mental disease to syphilitic involvement of the central nervous system.

Another erroneous conception in connection with neurosyphilis has been that of the period of incubation, or the time elapsing between the appearance of the initial lesion and the involvement of the structures of the brain and spinal cord. Formerly we were taught to regard syphilis of the nervous system as a late manifestation, appearing anywhere from ten to twenty years after infection. This has been misleading and undoubtedly productive of much harm and has caused many cases to be overlooked and conveyed to both physician and patient a sense of false security that has resulted disastrously. The fact is that there is no period of exemption after infection, and while cases of neurosyphilis may be encountered, twenty, thirty and even forty years after the initial lesion and while many syphilitic individuals may die from other causes and thereby escape luetic brain and cord accidents, on the other hand the prodromata of neurosyphilis may occur at any date after the first few months and the first year shows the greatest

*Read before the Luzerne County Medical Society, Wilkes-Barre, Penn., November 19, 1925.

number of cases and these patients are frequently treated as neurasthenics until irreparable damage has been done and the period which offered a fair chance of effecting a cure has passed.

We have under observation at the present time a patient on furlough from the Danville State Hospital who is being treated for cerebral syphilis. This man was one of five who were infected by the same woman on the same night and all but he have died from neurosyphilis within five years.

CLASSIFICATION

From the pathological standpoint, syphilitic nerve lesions may be grouped under two broad classifications:

1. Meningovascular lesions which, like specific lesions elsewhere, originate in the connective tissue or bloodvessels and only secondarily affect the parenchyma. These lesions manifest themselves early in a disturbance of function and not until much later as a result of neglect or failure of treatment do they destroy the essential cells and fibres of the part.

2. Parasyphilitic lesions, which affect generally the cortical parenchyma, are always degenerative in character, and are marked by glial increase and Wallerian degenerations and failure to respond but temporarily to specific therapy.

Either of these lesions may involve primarily and remain confined to either the brain or spinal cord or both of these structures may be invaded at some period of the disease.

Clinically the meningovascular lesions manifest themselves as cerebrospinal syphilis which is further divided for descriptive study into cerebral syphilis and spinal syphilis according to the predominance of distinct cerebral or spinal symptoms, for while most cases of spinal syphilis show evidences of more or less brain involvement at some period, the cerebral type is frequently devoid of spinal complications.

Parasyphilitic lesions are generally manifested as paresis or tabes dorsalis either of which may be acquired or hereditary.

CEREBRAL SYPHILIS—SYMPTOMATOLOGY

While the general symptoms of well developed cerebral syphilis show certain modifications as the result of the particular type of lesion that may be present, there are in all types as a rule a prodromal period that is of the utmost importance to recognize and during which the patient is seeking relief at the hands of his family physician.

These early manifestations are headache, dizziness, disturbances of sleep, irritability, inability to apply one's self continuously to one's work, lack of interest in work, a failure of general physical health. In other words the patient presents the generally accepted symptoms of neurasthenia.

The neuropsychiatrist frequently sees such patients who as Dr. Jelliffe has so aptly remarked, "have had their teeth pulled, their tonsils gouged out, their eye glasses refitted or eye muscles cut, their cervices amputated, their ovaries removed, from nine inches to six feet of gut cut out, all of the endocrine glands dispensed, weeks of colonic irrigation with or without electrical rigmaroles. These patients often go through every fad and fiction of medicine before a competent examination reveals the underlying factor."

If we examine carefully into the above symptoms of the supposed neurasthenic we find that the headache is of a very disagreeable character, varying in intensity from a dull, boring pain to one that is atrocious in its severity. It is inconstant, intermittent, frequently worse at night than in the day time. Beginning often in a localized area, which is marked by tenderness on percussion, it may gradually invade the entire head and frequently defying all sedatives save morphine, last for months and yet yield in a few days to mercury and the iodides.

Vertigo in shorter or longer attacks is frequently associated with the headache and is always increased by mental or physical work. In some cases it is the only single symptom that manifests itself during the prodromal period, and therefore continued dizziness in a young or middle aged adult should always arouse the suspicion of brain syphilis.

Sleep may be modified in two ways. There is either insomnia or abnormal sleepiness. The insomnia often occurs early before the beginning of headaches and is of course increased as a result of the pain as this appears. Abnormal sleepiness is also of great significance. This condition may occur early. The patient will frequently drop to sleep at any time during the day over his desk or his paper or even at his meals and even when aroused at night by the cephalalgia he will frequently drop back into a heavy stuporous sleep.

With the above distressing manifestations we find as a logical accompaniment mental and physical changes. The patient becomes dull, more or less apathetic, disinclined for study, work or social enjoyment, the memory is frequently impaired as the result of lack of concentration and fixation of ideas, he looks and acts and feels depressed or indifferent. The appetite is lost, strength declines, he loses weight and the skin and mucous membranes grow pale and anemic.

Often at this period definite neurological signs are present and the alert physician will frequently find in a drooping eyelid, unequal pupils or tingling, twitching or fine tremors in an arm or leg or about the muscles of the mouth objective evidences that will label the condition almost conclusively.

If the disease progresses beyond the prodromal period, its further development is marked by evidences of meningitis, arteritis, or gummatous formation. At this time the neurological signs are prominent. Pupillary inequalities or sluggishness in reaction to light or accommodation are present, ptosis and squints are frequent and diplopia is sometimes complained of as the result of cranial nerve involvement, monoplegias or hemiplegias and aphasias make their appearance and these may be transitory and partial or complete and permanent. Epileptiform convulsions develop which may be of a petit mal, grand mal, or Jacksonian type and during this period the patient may at any time exhibit all the symptoms of an acute meningitis or death may result from rupture of a large basal vessel or thrombosis in the circle of Willis.

MENINGOVASCULAR SPINAL SYPHILIS—SYMPTOMATOLOGY

In considering meningovascular syphilitic lesions of the spinal cord, we should bear in mind the fact

that practically all cases sooner or later present evidences of cerebral involvement and in fact a diagnosis of syphilis of the cord often depends upon this association. In primary syphilis of the spinal cord and its membranes, the disease is at first limited to the meninges, nerve roots and bloodvessels, just as are the lesions of cerebral syphilis; changes in the cord itself being always secondary and in a sense mechanical.

Clinically, meningovascular spinal syphilis presents the symptoms of a spinal meningitis or meningomyelitis. These symptoms are principally pain and palsies. The pains are early manifestations and like those of cerebral syphilis are often intense and show a tendency to noctural exacerbation. They are as a rule located in the lower extremities and are generally associated with an almost intolerable rachialgia in the lower part of the back. These pains are due to nerve root involvement and may be marked by tenderness along the nerve trunks and by herpes and glossy skin. Sensory disturbances are likewise present and consist of formication, numbness and coldness of the parts affected. Palsies as a rule in the early stages are rarely complete and confined generally to the lower extremities with partial loss of function and general heaviness and clumsiness upon attempts to walk. Later as a result of either extension or pressure from chronic meningeal thickening, the reflex excitability of the cord will be increased and will show itself by increased patellar reflexes, at times a positive Babinski, Oppenheim or Chaddock signs and a spastic paralysis below the hips. As the cord itself becomes involved there will be developed myelitic syndromes with some loss of sensation and vesical and rectal incontinence.

PARASYPHILITIC LESIONS

In the second group of neurosyphilitic conditions, namely the parasyphilitic type, we are dealing with a condition in which the parenchyma of the central nervous system has been invaded by the treponema with a resultant degeneration of the essential constituents of the brain and cord, and in consequence we may have a varied clinical picture dependent upon the preponderance of involvement of various tracts and centres. Thus if the anterior spinal horns are affected we may have the clinical picture of a progressive muscular atrophy with its characteristic paralysis and wasting. If the lateral tracts are involved the evidence of a spastic peraplegia will be most prominent with the characteristic spastic gait, loss of function and increased patellar reflexes. If the posterior columns are involved, we have the tabetic syndrome and if the brain cortex is invaded there may be epileptiform attacks and the mental and neurological picture of paresis.

TABES DORSALIS—SYMPTOMATOLOGY

Tabes dorsalis or locomotor ataxia may develop in from a few months to fifty years after the initial lesion and may show its characteristic symptoms at any period between fifteen and seventy years of age. The great majority of cases, however, occur between the ages of thirty and forty-five years and from five to fifteen years after infection.

While in this disease the clinical picture may be more or less varied and while there is no one symptom that may not be absent in a given case and very few neurological signs that may not be present in other neurological conditions the following syndrome may be relied upon for practical purposes:

1. *Pain.*—This may be of a sharp neuralgic character generally appearing in the lower extremities and often preceding all other symptoms, there may also be crises affecting various viscera, the most common being the gastric crises consisting of sudden violent gastric pain, radiating in all directions and in severe attacks accompanied by nausea, vomiting and great prostration. These pains may last for a few hours or a few days and then disappear for weeks or months to recur at irregular intervals. Some cases of tabes begin with such crises and failure to recognize their nature has led to unjustified laparotomy.

2. *Parasthesias and related sensory disturbances.*—These consist of tingling, numbness, crawling sensations, flashes of hot and cold, some impairment of tactile sensibility which causes the sensation in the upper extremity of wearing a glove and in the lower of walking on a carpet of velvet, and in some cases the superficial pain sense is lost and the patient cannot recognize the prick of a pin or appreciate the difference between hot and cold.

3. *Ataxia.*—This is one of the most prominent signs of sensory involvement and occurs as a result of degeneration of the fibres conducting the impulses from the joints and muscles to the chief organ for their coordination, the cerebellum, and as a result there is an imperfect knowledge of the position of the joints and of the states of muscular tension necessary to the performance of motor functions. Hence if the patient closes his eyes and abducts his arms to a right angle with the trunk he is unable to find his nose with his index finger or approximate the index fingers of both hands save with great difficulty. Likewise he is unable to find one knee with the other heel, if his legs are moved in bed cannot tell in what position they are placed and if the fingers or toes are moved is unable to tell their position. The gait also becomes altered and these changes are very characteristic. The patient first complains of difficulty in going up and down stairs, or finds himself insecure on uneven surfaces. At night he is unable to get about save with some difficulty and soon finds that in the daytime he must keep his eyes either on his legs or the surface on which he is walking in order to coordinate his movements. Later he finds it necessary to walk with a cane and he can always be heard before he is seen as a result of the sound caused by bringing the heel first to the ground and then the balance of the foot with a pronounced stamp.

Romberg's sign is practically always present at some stage of the disease and the patient is unable when standing with heels and toes together and eyes closed to maintain his equilibrium without swaying.

4. *Alteration of tendon reflexes.*—The patellar and achilles reflexes are diminished early in the disease and finally as a rule abolished. This alteration may begin in one side and so remain for a greater or less period of time but gradually the reflex excitability is entirely lost in both lower extremities.

5. *Changes in pupillary reflexes.*—One of the early signs and frequently the first to make its appearance is the Argyll-Robertson phenomenon, which consists

of a failure of the pupils to contract when exposed to direct light stimulation, while continuing to respond normally to accommodation.

6. *Visceral disturbances.*—The bladder is involved as a rule at some period in the disease and the usual manifestations are incontinence and cystitis. In some cases there may also be loss of control of the anal sphincter with resultant fecal incontinence.

Gradually and over a period of years, as a rule ten or fifteen, the physical strength fails, the patient becomes bedridden and death occurs either as the result of intercurrent disease or from complicating bulbar, cardiac or renal conditions.

PARESIS—SYMPTOMATOLOGY

General paresis is an organic disease of the brain of an inflammatory and degenerative nature, involving in the main the leptomeninges and cortex, and manifesting itself by certain physical and neurological signs and a progressive mental deterioration on which may be engrafted various other symptoms of mental disturbance.

Among the early symptoms of this disease are a gradual change of character, with a slight but progressive failing of mental capacity. The patient is unable to apply himself to his work. Mental application of any kind brings on fatigue. Slight memory defects are apparent. Business engagements are forgotten and errors of judgment become quite marked. The patient will enter into all sorts of financial relations with various people, risk his savings on hair-brained schemes. There is often alteration in his morale, and he may use alcohol to excess or become the companion of prostitutes, and see nothing out of the way in his conduct. He becomes careless about his personal appearance, wears soiled linen, forgets his collar or tie, and engrafted on these signs of beginning deterioration may be symptoms of emotional excitement or depression and delusions of a hypochondriacal or grandiose nature, together with hallucinations and illusions.

Neurologically there is exaggeration or diminution of the patellar reflex of one or both sides. The pupils, while reacting to accommodation, are frequently sluggish in their reaction to light and they may show inequality and irregularity in outline. A very slight defect of speech may be noticeable when test phrases are employed, and there may be a slight tremor about the muscles of the mouth during emotional excitement or in attempting to say a difficult word.

Cases of paresis, as a rule, when they reach state hospitals, are beyond the hope of cure, although much may be hoped for if the disease is recognized early, and in making a diagnosis two things should always be borne in mind:

1. That as a gross organic, metasyphilis disease of the brain, the mental symptoms alone must not be taken as a guide. The neurological signs, particularly those in the field of motor disturbance, should always be sought for.

2. The expansive delusions of great wealth, power, and strength, so often described as classical symptoms of the disease, do not necessarily form a part of it, and we may have instead of these, in addition to the general beginning, mental deterioration, a delusional system and emotional conditions similar to the other psychoses.

DIFFERENTIAL DIAGNOSIS

Paresis may be differentiated from locomotor ataxia, if we bear in mind that in the latter we are dealing with a sclerosis of the posterior columns of the cord and hence we have present early, shooting pains in the legs, sense of constriction about the body and visceral crises, together with a progressive optic atrophy. There is an absence of the tremor, speech defect, and mental deterioration.

Cerebral syphilis of the diffuse meningitic type presents headache, dizziness, somnolence, localized paralysis, especially of the cranial nerves below the third, and often a spastic and partly paralytic condition of the lower extremities with increased knee jerks and a positive Babinski sign are present. In the endarteritic type, the clinical manifestations are essentially those of the cerebral arteriosclerosis. In all forms of cerebral syphilis, the mental manifestations are less prominent than in paresis, and the personality is much better preserved, as is shown by the social reactions, ethical sense, judgment and general behavior; while delusions and hallucinations are seldom encountered.

HEREDITARY NEUROSYPHILIS

In the above discussion we have been dealing with conditions produced by acquired syphilitic infection. Hereditary syphilis is likewise capable of producing any or all of the conditions that follow the acquired infection and hence we meet not uncommonly with juvenile tabes and paresis. In addition we may likewise have various degrees of mental defect or of psychopathic personality. Any of these conditions may appear in the early years of life or be postponed until puberty or even until the twentieth or thirtieth year.

AIDS IN EARLY DIAGNOSIS

In view of the large number of individuals who develop neurosyphilis, the insidious manner of its onset and the varied clinical signs which it presents, in what way may we best proceed in the matter of its early recognition?

1. Bearing in mind that from five to ten per cent. of the population of this country are syphilitic, we should consider the possibility of its existence in every patient who seeks our advice and the absence of a history of primary infection should not be regarded as conclusive evidence that the disease is not present for infection may occur without the development of any appreciable lesion and furthermore the majority of neurosyphilitic patients do not show secondary lesions.

2. It should be remembered that as a rule prodromal manifestations are present over a period of months and sometimes years and the patient with a stubborn neuritis, or neurasthenia, obstinate headaches, periodic attacks of gastric or vesical pain will frequently show upon critical examination syphilis as the etiological factor.

3. Apoplectic stroke before the age of forty and epileptiform convulsions beginning after the age of twenty-five years are in the majority of instances due to syphilitic involvement of the central nervous system and farther the epileptic and choreic child should always be investigated neurologically and serologically as supposed epilepsy and chorea in childhood is often in reality juvenile paresis.

4. A neurological examination should be made in every case in which there is a history or suspicion of syphilitic infection. In every patient who applies for treatment for syphilis, the physician should acquaint himself with the pupillary reactions, the tendon reflexes, the coordination of gait, station and speech and the findings should be recorded to the end that at a later period they may serve as a definite check upon neurological findings.

5. Pregnancy and blood Wassermann should be synonymous terms. If the findings are positive, a second examination should be made as a check against possible error and if again positive results are had, specific therapy should employed with a view of preventing the disease in the child.

6. A Wassermann examination of the blood should be made of every patient applying for treatment, irrespective of what condition he consults the physician for, and in cases of syphilis this should be supplemented by a serological, chemical and cytological examination of the spinal fluid, and while these tests are not infallible and negative findings should not be considered conclusive evidence of freedom from infection in the presence of well developed neurological signs, on the other hand in the great majority of cases these tests will confirm the diagnosis and often a positive spinal fluid will give the earliest clue to involvement of the brain and spinal cord. This course is now being pursued in the majority of our general hospitals and group clinics throughout the country and is a procedure that the majority of patients appreciate.

The successful treatment of neurosyphilis is one hundred per cent. preventive, for a diagnosis of cord or brain syphilis implies the recognition of a critical condition. If, however, the central nervous system has become involved and the patient is seen in the early stages of the condition, much may be expected from intensive treatment. This is especially true of the meningovascular type. Here the lesions are inflammatory and exudative and hence we may expect to secure a substantial control and often a practical cure. When, however, the organisms have invaded the parenchyma of the brain and cord and escaped from the fibrovascular structures, our present remedies seem incapable of reaching them in sufficient quantity to work their destruction, although even in these cases early treatment may result in prolonging the economic efficiency and life of the patient and at times produce remissions for indefinite periods of time. The therapeutic agents and procedures advocated in the treatment of neurosyphilis are as varied as the hues of the rainbow. These include the arsenical preparations, various bismuth salts and compounds and most recently the injection of the plasmodium malariæ, and the methods of introduction into the body have consisted of intraspinous, intraventricular, intramuscular and intravenous injections, all of which have been supplementary to the tried and proven stand bys, mercury and the iodides in varying forms.

A discussion of the relative value of these agents and the various methods of their administration would involve a lengthy presentation of many varied and opposing observations. On the whole it may be asserted that for practical purposes arsenic in the form of arsphenamine or neoarsphenamine used in conjunction with mercury and the iodides has given the most satisfactory results. The best methods of introducing these antisyphilitic remedies into the body are probably the intravenous injection of from 0.6 to 0.9 grm. of arsphenamine once weekly for a period of from six to eight weeks, this to be followed by mercurial inunctions and potassium iodide by mouth for a like period, being guided by the regular precautions in the use of these latter remedies. This alternating treatment should be carried on over an indefinite period, the length of time being determined by the clinical signs and blood and spinal fluid evidences of improvement. It should be borne in mind that a patient who has once shown evidences of syphilis can never be regarded as permanently cured and if his best interests are to be served he must submit himself to neurological and serological investigations at regular intervals throughout life.

In conclusion, I would again stress the fact that neurosyphilis and its treatment resolves itself into a conscientious and scientific study of every patient that presents himself to the general practitioner for advice and a determination of the presence or absence of syphilis in every case before a definite course of treatment is outlined.

Tryparsamide and Paresis.—Sidney I. Schwab (*Medical Clinics of North America,* July, 1925) says that obviously no definite conclusions as to the therapeutic efficacy of tryparsamide can be made at the present time, but as a result of his experiences in five cases of paresis certain tentative ideas are worth noting. Tryparsamide is a drug that must be used with care and careful selection of cases. In paresis a study of the type of case and its progress should be made before the drug is given. In extremely advanced cases in which mental deterioration is excessive and where the cerebral tissue degeneration is very evident, as measured by symptoms and findings, nothing can be expected. Optic nerve changes are to be regarded as contraindications for tryparsamide treatment unless the case would seem to promise favorable reaction to the drug. In the presence of optic nerve changes in which mental deterioration is not far advanced and in which conduct and behavior are not primarily affected—to such an extent at any rate that adaptation may not be hoped for—tryparsamide may be given in small doses and in lengthened intervals. Tryparsamide in association with arsphenamin and mercury offers in selected cases and selected types of paresis the most promising method of treatment that is at present available. The remarkable changes for the better in conduct and in general physical wellbeing are evidences of the fact that this drug does exercise a definite influence upon the cellular defensive mechanism. In this particular feature it is almost a unique contribution to the pharmacology of syphilitic disease of the nervous system.

An attempt has been made in the clinical cases presented to suggest that paresis is largely a matter of abnormal conduct and behavior and that the final diagnostic test should be based upon a study of these abnormal reactions rather than upon any rigid interpretation of the findings in the spinal fluid and blood. In this way a clinical estimation of paresis can be built up which has for its purpose the study of the total personality of the patient rather than incidental findings and unimportant symptomatic features.

clearly indicated. Would the duodenal tube favor the patient and attending doctors by going through the various passages, narrow and wide? In view of the patient's extreme inanition and beginning hunger delirium, the mildest procedure must be tried. A cutting operation, even under local anesthesia, seemed clearly contraindicated, except it should become imperative.

Dr. Einhorn introduced a long duodenal tube with a special tip of smaller size, which soon passed the midgastric stricture and evidently entered the small intestine, inasmuch as clear bile was withdrawn after forty-eight hours, proving that it was in the jejunum. From the moment that the cardiac pouch had been put out of commission and at rest, vomiting ceased as by magic. Proper scientific feeding was begun at once, most carefully and at regular intervals and was well borne. The patient felt relieved from her fear and despair. The battle was won. A few days later she was out of bed.

After some discussion the patient was persuaded to allow the tube to remain in place for fully three weeks. When removed on June 21st, vomiting did not return. To keep the patient at the hospital and slowly prepare her for the second contemplated operative step was out of question. She insisted on going home as soon as possible, and was discharged on June 26th. She promised to call at the office for observation.

When seen at the office on December 2d she had gained fifteen pounds in weight (weighing ninety-nine pounds). A casual hint at a second operation was flatly rejected. She was completely satisfied with her present condition.

She was not seen after June 25th. On inquiry she was reported, under date of April 30, 1925, to be eating comparatively little in order to avoid distress; felt very well; weighed ninety-six pounds.

Surely, the duodenal tube here acted as a life saver in the nick of time and will likely do so again under similar circumstances.

A recent observation of a more subacutely occurring vicious circle, subsequent to a posterior gastroenterostomy, which was successfully overcome by the duodenal tube, may be here cited as a further example of the value of jejunal feeding by means of a long duodenal tube in the presence of persistent vomiting during the days immediately following the operation.

Case II.—A male, sixty years old, had shown signs of benign pyloric stenosis for more than twelve years; conservative treatment at the hands of Dr. Einhorn kept him going. Now operation was indicated. On February 26, 1925, typical posterior gastrojejunal anastomosis with a short loop was carried out by me. Operation was well borne; there was no reaction whatever. Beginning on the fifth day, with increasing quantity of nourishing food administered by mouth, vomiting of large masses containing a great amount of bile, occurred once or twice a day. Gastric lavage with colonic irrigation and proper feeding kept it in check to some extent. Still, the patient was slowly losing ground. A long duodenal tube was passed by Dr. Einhorn. It slipped nicely into the intestine, so that regular jejunal feeding and the instillation of quarts of Ringer's solution could be taken up. Patient recuperated quickly. When the tube was withdrawn at the end of the third week, normal, continuously downward current of food had been established. Soon the patient went home. According to recent information he is in splendid condition, has gained more than fifteen pounds in four weeks and enjoys life.

Observations like these are to my mind of great importance to the surgeon. In the course of his work he will now and then come across a patient who develops the socalled vicious circle after gastroenterostomy, although the operative technic was the same in every detail as in a score of other similar operations in which there was no vomiting: short loop, wide anastomosis, borders of rent in transverse mesocolon stitched to stomach instead of jejunum, etc. The cause of such persistent vomiting cannot be explained except on individual lines: the unavoidable entrance of some bile into the stomach, acting as an emetic in this particular case, although usually it is seen to become a not unwelcome guest of the stomach after gastroenterostomy and likely, on account of its alkalinity, plays an important rôle in many cases of duodenal ulcer in hastening the final healing of the ulceration and avoiding the formation of a marginal ulcer.

No doubt a mechanical cause for persistent vomiting during the first days after operation must also be thought of, e. g., a slight kink at the distal corner of the anastomosis, a temporary postoperative acute edema of the sutured portion of the gastrojejunal wound, which may easily prevent liquid and soft food within the stomach from entering the distal portion of the jejunum, but rather forcing it into the afferent portion of the loop, viz., into the duodenum.
